Preface to 1st Edition

This encyclopedia provides, we believe, a comprehensive and up-to-date explanation of the most important spectroscopic and related techniques together with their applications.

The *Encyclopedia of Spectroscopy and Spectrometry* is a cumbersome title but is necessary to avoid misleading readers who would comment that a simplified title such as the “Encyclopedia of Spectroscopy” was a misnomer because it included articles on subjects other than spectroscopy. Early in the planning stage, the editors realized that the boundaries of spectroscopy are blurred. Even the expanded title is not strictly accurate because we have also deliberately included other articles which broaden the content by being concerned with techniques which provide localized information and images. Consequently, we have tried to take a wider ranging view on what to include by thinking about the topics that a professional spectroscopist would conveniently expect to find in such a work as this. For example, many professionals use spectroscopic techniques, such as nuclear magnetic resonance, in conjunction with chromatographic separations and also make use of mass spectrometry as a key method for molecular structure determination. Thus, to have an encyclopedia of spectroscopy without mass spectrometry would leave a large gap. Therefore, mass spectrometry has been included. Likewise, the thought of excluding magnetic resonance imaging (MRI) seemed decidedly odd. The technique has much overlap with magnetic resonance spectroscopy, it uses very similar equipment and the experimental techniques and theory have much in common. Indeed, today, there are a number of experiments which produce multidimensional data sets of which one dimension might be spectroscopic and the others are image planes. Again the subject has been included.

This led to the general principle that we should include a number of so-called spatially-resolved methods. Some of these, like MRI, are very closely allied to spectroscopy but others such as diffraction experiments or scanning probe microscopy are less so, but have features in common and are frequently used in close conjunction with spectroscopy. The more peripheral subjects have, by design, not been treated in the same level of detail as the core topics. We have tried to provide an overview of as many as possible techniques and applications which are allied to spectroscopy and spectrometry or are used in association with them. We have endeavoured to ensure that the core subjects have been treated in substantial depth. No doubt there are

omissions and if the reader feels we got it wrong, the editors take the blame.

The encyclopedia is organized conventionally in alphabetic order of the articles but we recognize that many readers would like to see articles grouped by spectroscopic area. We have achieved this by providing separate contents lists, one listing the articles in an intuitive alphabetical form, and the other grouping the articles within specialities such as mass spectrometry, atomic spectroscopy, magnetic resonance, etc. In addition each article is flagged as either a “Theory”, “Methods and Instrumentation” or “Applications” article. However, inevitably, there will be some overlap of all of these categories in some articles. In order to emphasize the substantial overlap which exists among the spectroscopic and spectrometric approaches, a list has been included at the end of each article suggesting other articles in this encyclopedia which are related and which may provide relevant information for the reader. Each article also comes with a “Further Reading” section which provides a source of books and major reviews on the topic of the article and in some cases also provides details of seminal research papers. There are a number of colour plates in each volume as we consider that the use of colour can add greatly to the information content in many cases, for example for imaging studies. We have also included extensive Appendices of tables of useful reference data and a contact list of manufacturers of relevant equipment.

We have attracted a wide range of authors for these articles and many are world recognized authorities in their fields. Some of the subjects covered are relatively static, and their articles provide a distillation of the established knowledge, whilst others are very fast moving areas and for these we have aimed at presenting up-to-date summaries. In addition, we have included a number of entries which are retrospective in nature, being historical reviews of particular types of spectroscopy. As with any work of this magnitude some of the articles which we desired and commissioned to include did not make it for various reasons. A selection of these will appear in a separate section in the on-line version of the encyclopedia, which will be available to all purchasers of the print version and will have extensive hypertext links and advanced search tools. In this print version there are 281 articles contributed by more than 500 authors from 24 countries. We have persuaded authors from Australia, Belgium, Canada, Denmark, Finland, France, Germany, Hungary, India, Israel, Italy, Japan, Mexico, New Zealand, Norway, Peru, Russia, South Africa, Spain, Sweden,

Switzerland, The Netherlands, the UK and the USA to contribute.

The encyclopedia is aimed at a professional scientific readership, for both spectroscopists and non-spectroscopists. We intend that the articles provide authoritative information for experts within a field, enable spectroscopists working in one particular field to understand the scope and limitations of other spectroscopic areas and allow scientists who may not primarily be spectroscopists to grasp what the various techniques comprise

in considering whether they would be applicable in their own research. In other words we tried to provide something for everyone, but hope that in doing so, we have not made it too simple for the expert or too obscure for the non-specialist. We leave the reader to judge.

John Lindon
John Holmes
George Tranter

Preface to 2nd Edition

The first edition of the Encyclopedia of Spectroscopy and Spectrometry, published as a print version in 1999, comprised around 300 articles written by experts in their fields and covered as comprehensive a range of subjects as we were able to commission at the time. I, and my co-editors John Holmes of the University of Ottawa, Canada, and George Tranter, then at GlaxoWellcome in the UK, endeavoured to attract authors who could provide up-to-date explanations of the most important spectroscopic and related techniques along with details of their many fields of application.

To reiterate our strategy at the time, we felt it necessary to include topics that, in the strict definition of the word, were not spectroscopy. Thus, and obviously, we included mass spectrometry, and expanded the title to encompass spectrometry. Even this title was not completely accurate because we felt that subjects such as magnetic resonance imaging that use many of the same principles as spectroscopy should also be included and this led to a section of the encyclopedia on spatially resolved methods. Some of these articles are further away from spectroscopy and spectrometry than others, but were included for completeness and because we felt that interested readers would like to have an entry point to these subjects.

Around a decade later, we have completed a major update of this work and this has resulted in an on-line work that has over a 100 new and updated articles. Some of the articles have of course not needed to be changed, particularly those that explain the theory behind the

various techniques. However, technology has moved on apace in the last 10 years and many major advances in spectroscopy and spectrometry have been achieved. In this new edition, we hope that we have captured these. One of the original editors, John Holmes, was no longer available to us and we are very fortunate to have attracted David Koppenaal from the Pacific Northwest National Laboratory in the USA as a new co-editor. With this new editorial team we have reviewed all of the articles in the first edition and commissioned updates for many of these. We have also tried to commission articles on subjects that were not covered in the first edition, reflecting both gaps in success in getting articles last time around and also the fact that there are now many new approaches that did not exist 10 years ago.

The encyclopedia is aimed at a professional scientific readership, and we hope that the articles are useful both for experts within a given field, and that they will also provide an entry point for an interested person to find out more about a subject in which they are not perhaps so expert. It is possible that in trying to provide such wide accessibility that we have compromised on the depth for the expert and the breadth for the non-expert. We do not believe this to be so and we leave the reader to judge.

John Lindon, Imperial College London, UK
George Tranter, Chiralabs Ltd, Oxford, UK
David Koppenaal, Pacific Northwest National
Laboratory, Richland, WA, USA

Acknowledgements

This major revision of the encyclopedia to produce the second edition could not have been successful without the involvement of many people from different backgrounds and with different skills.

First I have to thank all those authors who took considerable time and effort to either write new articles for us or to update their previously written articles (many of these updates being in essence new articles). We are indeed grateful to them because without them there would be no encyclopedia. We know that they are all very busy scientists, many being leaders in their field and we thank them for their commitment to making this work a success.

Next, I would like to thank all of the people at Elsevier for their unfailing enthusiasm for this project and for their efficiency and professionalism in seeing it through. Adrian Shell and Bob Donaldson were very helpful in overseeing the project; they brought their wealth of experience to our meetings and guided us past many pitfalls. The

commissioning editor Hannah Rutland and her colleagues Fiona Geraghty and Will Smaldon were always helpful and efficient and we are also very grateful for their cheerfulness throughout. Mike Nicholls the production project manager and Rick Williamson in the USA also must be thanked for their valuable contributions in making the production process so smooth.

Finally, I personally would like to acknowledge the close cooperation and help from my co-editors George Tranter and Dave Koppenaal. Without them, this project would not have been achievable. Our interactions, by phone, by email, by teleconference and in meetings, were always very productive, and importantly very happy and cheerful. We had a great time producing this new edition!

Disclaimer

This encyclopedia is a guide providing general information concerning its subject matter; it is not a procedures manual. The readers should consult current procedural manuals for state-of-the-art instructions and

applicable government safety regulations. The publisher and authors do not accept responsibility for any misuse of this encyclopedia, including its use as a procedural manual or as a source of specific instructions.

Guide to Use of the Encyclopedia

Structure of the Encyclopedia

The material in the encyclopedia is arranged as a series of articles in alphabetical order. They are also linked together based on the type of spectroscopic approach.

There are three features to help you easily find the topic you're interested in: an alphabetical contents list, cross-references to other relevant articles within each article and a full subject index.

1. Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2. Cross-references

All of the entries in the encyclopedia have been cross-referenced. The cross-references which appear at the end of an entry as a *See also* list, serve four different functions:

- i. To draw the readers attention to related material in other entries
- ii. To indicate material that broadens and extends the scope of the article
- iii. To direct readers to other articles by the same author(s)

- iv. To link the theory, instrumentation and applications of a given technique

Example

The following list of cross-references appears at the end of the entry "Overview of NMR-based Metabonomics".

Analytical Methodology Standards for Metabolomics, Cells Studied by NMR, ^1H MAS NMR Spectroscopy of Tissues, *In Vivo* ^1H MRS Applications, Metabonomics in Food Science, MS Based Metabonomics, NMR Pulse Sequences, NMR Relaxation Rates, NMR Spectrometers, Solvent suppression Methods in NMR Spectroscopy.

3. Index

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4. Contributors

At the start of each volume there is list of the authors who contributed to all volumes.

Electron Diffraction Theory and Methods	<i>István Hargittai, Magdolna Hargittai</i>	461
Electronic Components, Applications of Atomic Spectroscopy	<i>John C Lindon</i>	466
Electrospray Ionization in Mass Spectrometry	<i>Keqi Tang, Jason S Page, Ryan T Kelly, Ioan Marginean</i>	467
Ellipsometry	<i>GE Jellison Jr</i>	475
Enantiomeric Purity Studied Using NMR	<i>Thomas J Wenzel</i>	484
Environmental and Agricultural Applications of Atomic Spectroscopy	<i>Michael Thompson, Michael H Ramsey</i>	494
Environmental Applications of Electronic Spectroscopy	<i>John W Farley, William C Brumley, DeLyle Eastwood</i>	502
EPR Imaging	<i>LH Sutcliffe</i>	510
EPR, Methods	<i>Richard Cammack</i>	518
EPR Spectroscopy, Theory	<i>Christopher C Rowlands, Damien M Murphy</i>	531
Exciton Coupling	<i>Nina Berova, Nobuyuki Harada, Koji Nakanishi</i>	542

F

Far Infrared Spectroscopy Applications	<i>James R Durig</i>	559
Fast Atom Bombardment Ionization in Mass Spectrometry	<i>Magda Claeys, Jan Claereboudt</i>	566
Fibre Optic Probes in Optical Spectroscopy, Clinical Applications	<i>Urs Utzinger, Rebecca R Richards-Kortum</i>	573
Fibres and Films Studied Using X-Ray Diffraction	<i>Watson Fuller, Arumugam Mahendrasingam</i>	589
Field Ionization Kinetics in Mass Spectrometry	<i>Nico MM Nibbering</i>	599
Flame and Temperature Measurement Using Vibrational Spectroscopy	<i>Kevin L McNesby</i>	608
Fluorescence Microscopy, Applications	<i>Fred Rost</i>	619
Fluorescence Polarization and Anisotropy	<i>GE Tranter</i>	625
Fluorescence Theory	<i>Karen G Fleming</i>	628
Fluorescent Molecular Probes	<i>F Braut-Boucher, M Aubery</i>	635
¹⁹ F NMR, Applications, Solution State	<i>Claudio Pettinari, Giovanni Rafaiani</i>	645
Food and Dairy Products, Applications of Atomic Spectroscopy	<i>NJ Miller-Ihli, SA Baker</i>	654

Food and Nutritional Science, Applications of Magnetic Resonance	<i>John P M van Duynhoven</i>	663
Food Properties, Applications of NMR	<i>Brian Hills</i>	671
Food Science, Applications of Mass Spectrometry	<i>John P G Wilkins</i>	680
Forensic Science, Applications of IR Spectroscopy	<i>Núria Ferrer</i>	681
Forensic Science, Applications of Mass Spectrometry	<i>Rodger L Foltz, David M Andrenyak, Dennis J Crouch</i>	693
Forestry and Wood Products, Applications of Atomic Spectroscopy	<i>Cathy Hayes</i>	699
Fourier Transformation and Sampling Theory	<i>Raúl Curbelo</i>	709
Fourier-Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR MS)	<i>Errol W Robinson</i>	714
Fragmentation in Mass Spectrometry	<i>Hans-Friedrich Grützmacher</i>	720
FT-Raman Spectroscopy, Applications	<i>RH Brody, EA Carter, HGM Edwards, AM Pollard</i>	732
Functional MRI (fMRI)	<i>Scott A Huettel</i>	741

G

Gas Phase Applications of NMR Spectroscopy	<i>Nancy S True</i>	749
Geology and Mineralogy Applications of Atomic Spectroscopy	<i>Michael E Ketterer</i>	757
Glow Discharge Mass Spectrometry	<i>C Derrick Quarles Jr, Joaudimir Castro, R Kenneth Marcus</i>	762

H

Halogen NMR Spectroscopy (Excluding ^{19}F)	<i>Frank G Riddell</i>	771
Heteronuclear NMR Applications (As, Sb, Bi)	<i>Claudio Pettinari, Fabio Marchetti, Giovanni Rafaiani</i>	779
Heteronuclear NMR Applications (B, Al, Ga, In, Tl)	<i>Janusz Lewiński</i>	785
Heteronuclear NMR Applications (Ge, Sn, Pb)	<i>Claudio Pettinari</i>	798
Heteronuclear NMR Applications (La–Hg)	<i>Trevor G Appleton</i>	812
Heteronuclear NMR Applications (O, S, Se, Te)	<i>Ioannis P Gerothanassis</i>	816
Heteronuclear NMR Applications (Sc–Zn)	<i>Dieter Rehder</i>	824
Heteronuclear NMR Applications (Y–Cd)	<i>Erkki Kolehmainen</i>	834
High Energy Ion Beam Analysis	<i>Geoff W Grime</i>	844
High Pressure Studies Using NMR Spectroscopy	<i>Jiri Jonas</i>	854
High Resolution Electron Energy Loss Spectroscopy, Applications	<i>Horst Conrad, Martin E Kordesch</i>	865
High Resolution Gas Phase IR Spectroscopy Applications	<i>E Canè, A Trombetti</i>	877
High Resolution Gas Phase IR Spectroscopy Instrumentation	<i>Jyrki K Kauppinen, Jari O Partanen</i>	884
High Resolution Solid State NMR, ^{13}C	<i>Etsuko Katoh, Isao Ando</i>	894
High Resolution Solid State NMR, ^1H , ^{19}F	<i>Anne S Ulrich</i>	905
High Temperature Chemistry Applications of Mass Spectrometry	<i>Lev N Sidorov</i>	917

¹ H MAS NMR Spectroscopy of Tissues	<i>Julian L Griffin, Reza M Salek</i>	925
Hole-Burning Spectroscopy	<i>Jean Pierre Schermann</i>	931
Hole-Burning Spectroscopy Methods	<i>Josef Friedrich</i>	936
HPLC–NMR, Pharmaceutical Applications	<i>JP Shockcor</i>	946
Hydrogen Bonding and Other Physicochemical Interactions Studied by IR and Raman Spectroscopy	<i>AS Gilbert</i>	957
Hyperpolarization Methods and Applications in NMR	<i>Walter Köckenberger, Jörg Matysik</i>	963
Hyperpolarized Gases in NMR, Methods and Applications	<i>Martin H Deppe, Jim M Wild</i>	971
Hyphenated NMR, Methods and Applications	<i>Jerzy W Jaroszewski</i>	979
Hyphenated Techniques, Applications of in Mass Spectrometry	<i>WMA Niessen</i>	984

Introduction

Accelerator mass spectrometry (AMS) was developed for analyzing ^{14}C in environmental and archeological specimens in the 1970s (although it was first demonstrated in the 1930s). It is now principally used to measure only a handful of isotopes, although it is feasible to apply it to many additional analytes. AMS represents the marriage of high-energy physics with radioanalytical chemistry and finds applications in geoscience, environmental analysis, archeology, cosmochemistry, biosciences, medicine, material science, nuclear chemistry, and physics.

AMS employs a high-energy tandem accelerator to raise ion energies to the mega-electron-volt (MeV) range and enable complete destruction and avoidance of isobaric interferences. Typical AMS is thus capable of measuring very small isotope ratios, typically in the range of 10^{-10} to 10^{-15} (atomic ratio). Isotopes of interest include ^{14}C , ^{10}Be , ^{26}Al , ^{36}Cl , ^{41}Ca , and ^{129}I . Measured rare/natural ratios for these isotopes fall well below the $1\text{--}10^{-9}$ range measured with other mass spectrometers (except for laser-based systems with resonance ionization techniques, which can match the range of the AMS).

Accelerators were developed to bombard targets with energetic ions for fundamental physical science purposes. Researchers recognized that the techniques used to create, select, and direct ion beams in the mega-electron-volt energy range could be applied to measuring extremely small isotope ratios with high sensitivity and low background. The AMS technique provides extremely high selectivity and efficient rejection of interferences

with quantitative elimination of interference by molecular species. The initial acceleration of negative ions is responsible for this effect, as almost all molecular ions and many atomic isobars are unstable as negative ions at high energies. By comparison, all other mass spectrometric techniques suffer to varying degrees from isobaric interference from ionic molecules with nearly identical mass. High mass resolution can be applied to resolve molecular and isotopic ion species with small mass differences, but usually only at the cost of lower sensitivity and increased system complexity. High mass resolution can also be provided by recently developed ion–molecule reaction chemistry approaches, as demonstrated by collision/reaction cell ICPMS (inductively coupled plasma mass spectrometry). These techniques may offer isotope ratios measurements intermediate between conventional mass spectrometry and AMS.

Instrumentation

An AMS consists of an ion source, an input mass or momentum selector (usually a magnetic sector), a high-energy accelerator, a ‘stripper’ (a low-pressure gas or thin foil placed in the middle of the high-voltage region to remove/strip electrons from the incident ions), postaccelerator ion optics and mass selectors, and one or more detector systems. The high-energy accelerator is usually a tandem accelerator, which consists of two back-to-back high-energy accelerators with a stripper between the accelerators. The voltage increases from zero at one end to the middle and decreases to zero at the other end. Low-energy negative ions are injected into one end of the accelerator, are stripped of electrons, and are then reaccelerated to emerge as high-energy positive ions at the other end. This tandem acceleration arrangement allows both the ion source and ion detector regions to be operated at or near ground potential to simplify construction and electrical operation of the instrument.

Ions are typically produced using a secondary ion or sputter source, often using a Cs ion source (of the type usually employed in secondary ion mass spectrometry) to produce negative ions. These ions are extracted, focused, and initially accelerated to energies of 10–100 keV. The input mass selector directs a specific sputtered ion mass into the tandem accelerator, which then accelerates these negative ions to mega-electron-volt energies. A stripper in the central region of the accelerator dissociates molecular ions and removes multiple electrons from the ions to convert ingoing negative ions (elemental or molecular) into outgoing multiply-charged positive ions. These positive ions are further accelerated *by the same potential* and emerge from the back-end of the accelerator with energies that can reach above 30 MeV, depending on the accelerator base voltage (or potential) and the degree of ionization. Charge states of +10 or more can be produced, especially for heavy ions such as the actinides. After acceleration, additional ion optics and switching magnets are used to select the ion mass and charge state and to direct these ions into detectors for measurement.

Traditionally, AMS instruments have been very large owing to the size of standard accelerators. Path lengths from ion source to detector can be tens of meters, and total instrument footprints of $>150\text{ m}^2$ are typical. The high ion energy results in large differences in ion path angles and trajectories. After selection by mass, the ions are separated at centimeter-scale distances, in contrast to millimeter-scale separations produced in sector-based mass spectrometers. A Faraday cup detector is a common choice for the major isotope mass, whereas nuclear particle detectors (which include electron multipliers) count individual ions of the rare isotope. The high ion energies allow the use of detectors that can measure ion time of flight, ion energy, ion energy loss rate, and ion charge. Measurement of the ion charge/mass ratio provides additional selectivity for identifying the rare isotope. Recent improvements in AMS technology and techniques have allowed lowering of ion energy regimes to much lower values ($<1\text{ MeV}$), and consequent reduction in the size of AMS systems (to as low as 10 m^2 , an ~ 20 -fold reduction in size). Such systems, typically for ^{14}C determination, are now commercially available (National Electrostatics Corporation, Middleton, WI, USA).

In operation, the major and rare isotopes are measured sequentially by peak switching from one isotope to the other, as with other mass spectrometers, to determine atom ratios. The major isotope may produce a current in the microampere range, whereas the rare isotope produces a signal as low as a few counts per minute. The raw isotope ratio consists of counted pulses divided by integrated current. Calibration by measurement standards with known isotope ratios provides the factor to convert the raw ratio into an atom ratio.

Unique features of the AMS include ion energy in the mega-electron-volt range compared to kilo-electron-volt range or lower for other mass spectrometers, conversion of negative ions into positive ions, and generation of multicharged ions. The rare and major isotopes may be measured in different charge states, depending on the element under analysis, the need to eliminate isobaric interference, and the configuration of the instrument. However, the high energy poses safety and health considerations. The ions in an AMS have sufficient energy to produce radionuclides and radiation by nuclear reactions. Ions that strike various system parts (e.g., slits, deflection plates, and the inner walls of the vacuum system) can produce neutrons and x-rays. High voltages are associated with the ion source, deflection plates, and other parts of the instrument. These features require strict attention to radiological and electrical safety protocols and protection measures.

Sample Preparation/Presentation

The AMS technique is used to measure rare isotopes in samples that include air, water, ice, soil, minerals, meteorites, biological tissue, and archeological artifacts. Elemental sample sizes generally are in the milligram range to produce adequate rare isotope count rates for analysis.

Samples usually are processed before analysis to extract and purify the target element and its corresponding rare isotope. Some elements require the addition of a carrier for processing and yield determination, such as iodine for ^{129}I analysis in seawater, but care must be taken to measure the rare isotope background in the carrier. By comparison, carrier addition is avoided in the analysis of ^{14}C because samples have sufficient carbon for analysis and the goal is to measure the $^{14}\text{C}/^{12}\text{C}$ ratio in the sample. The purified element is converted into a solid form suitable for generating negative ions by Cs sputtering. The element of the rare isotope under analysis can be analyzed in molecular form or in reduced sample form, depending on the ionization characteristics of the element. For instance, carbon is analyzed as graphite, whereas iodine is analyzed as silver iodide. The resultant solid is pressed into a metal holder, commonly aluminum or copper and placed in the AMS ion source for analysis.

AMS Applications

The rare isotopes ^{14}C , ^{10}Be , ^{26}Al , ^{36}Cl , ^{41}Ca , and ^{129}I provide the bulk of the work performed by AMS laboratories, with the vast majority of the work being for ^{14}C . Recently, AMS has been applied to heavy-element analysis, for example, U and Pu. Other isotopes analyzed

Table 1 Experimental parameters for AMS

Isotope	Sample form	Measured isotope ratio	Detection limit	Carrier	Comments
^{14}C	Graphite	$^{14}\text{C}/^{12}\text{C}$	5×10^{-16}	None	—
^{10}Be	BeO	$^{10}\text{Be}/^9\text{Be}$	3×10^{-15}	Sometimes	—
^{26}Al	Al_2O_3	$^{26}\text{Al}/^{27}\text{Al}$	3×10^{-15}	None	—
^{36}Cl	AgCl	$^{36}\text{Cl}/^{35}\text{Cl}$, $^{36}\text{Cl}/^{37}\text{Cl}$	1×10^{-15}	Sometimes, chloride	Both ratios measured
^{41}Ca	CaH_2 or CaF_2	$^{41}\text{Ca}/^{40}\text{Ca}$	6×10^{-16}	None	—
^{129}I	AgI	$^{129}\text{I}/^{127}\text{I}$	3×10^{-14}	KI	—
U	U + Nb metal	$^{236}\text{U}/^{238}\text{U}$	1×10^{-12}	Nb metal	Berkovits et al. 2000
Pu	Pu + Fe oxide	$^{240}\text{Pu}/^{239}\text{Pu}$, $^{241}\text{Pu}/^{239}\text{Pu}$, $^{242}\text{Pu}/^{239}\text{Pu}$	< 1 fg	Fe oxide	Detection limit in atoms; multiple ratios analyzed

by AMS include tritium, ^{59}Ni , ^{90}Sr , and ^{205}Pb . Detection limits for AMS are typically given as limiting isotope ratios, the measured quantity in AMS. The overall ion transmission of a typical AMS is such that the absolute atom detection efficiencies are lower than either TIMS or ICPMS – on the order of 1 count per 100 000 atoms injected into the instrument. Nevertheless, the extremely low background of the AMS technique permits the detection and quantification at the sub-femtogram-level, which is comparable to the best ICPMS and TIMS analyses. Some experimental parameters are given in **Table 1** for the most commonly analyzed isotopes.

For some radionuclides, only the direct measurement is needed, based on calibration with a radionuclide standard and reference to the measured sample mass. For other radionuclides, the isotope ratio to its stable element is needed. An example of a more complex situation is measurement of the $^{14}\text{C}/^{12}\text{C}$ isotope ratio of an environmental or archeological sample in comparison to the modern atmospheric CO_2 value. This value must be adjusted for anthropogenic ^{14}C produced by atmospheric testing of nuclear weapons and by other nuclear operations, and also for changes in atmospheric CO_2 with cosmic-ray flux fluctuations over time. For an element such as Pu, which has no stable isotope, the total and absolute quantity is measured using isotope dilution mass spectrometry in which the sample is traced (or spiked) using ^{242}Pu or ^{244}Pu .

Introduction: The Need for Standardization

It would not be possible or probably profitable to survey the whole field of protocol standardization for spectroscopy in a single article given that this has been an area that has coevolved with the whole field of analytical science. There has always been a need to report how an experiment has been performed and that has to a large degree been carried out in a vocabulary that is representative of the field. However, if one takes the start of functional genomics as the beginning of a new drive for worldwide standardization of reporting, it becomes easier to place a start date to the area. The minimum information about a microarray experiment (MIAME) is a standardization of reporting protocols for

microarray transcriptomics experiments and was developed by the Microarray Gene Expression Databases (MGED) society. The aim of MIAME was to specify all the information required to interpret the results of microarray experiments without ambiguity and allow other researchers to reproduce the results obtained. The society originally met in 1999 and was hugely successful at achieving both community and publisher buy-in to the concept of a standardized description of reporting of microarray experiments. Indeed, today many of the top tier journals will not accept publication of a paper involving microarray data unless the data are submitted in a MIAME-compliant format. The MGED society has since expanded to include any functional genomic technology applied to genomic-scale studies of gene expression, binding, or modification.

In parallel to the developments of a standardized reporting protocol for microarray data, the European Bioinformatics Institute and the National Institute of Health in the USA both developed databases to house the experimental data generated by microarray data, found at <http://www.ebi.ac.uk/microarray-as/ae/> and <http://www.ncbi.nlm.nih.gov/geo/>, respectively. It was no accident these developments occurred in parallel, as there is a need to first define a standard reporting language (ontology) prior to the creation of a database. The necessity of good database design for bioinformatics has long since been appreciated in the various genome sequencing projects and for sequence comparisons across species. However, databases for transcriptomics, proteomics, and metabolomics pose a further complicating factor compared with genomic databases. While genomics, as applied to gene sequencing and comparisons, is not context dependent, the other ‘-omes’ will produce different profiles according to time, disease state, or interaction with biochemical/chemical/physical stimuli. This complicates the construction of any database, necessitating files which report information about the sample and context examined, the experimental procedure, and the hypothesis that was being tested, as well as information about how the data were acquired and processed. The generation of these meta datafiles (data to describe where the raw data came from) is a real challenge. Furthermore, for the database to be easily useable this information must be stored in a uniform format that simplifies any search routine required to retrieve the data, but not provide an extra cumbersome burden to the users who deposit the information.

Minimum Information about a Proteomic Experiment (MIAPE)

Following the successes of MIAME in the transcriptomic community, the Human Proteome Organization (HUPO), an international consortium of industry, academic, and government scientists, set out to extend standard reporting to proteomics. Central to this initiative has been how to best describe the analytical techniques used to measuring proteins largely by mass spectrometry-based approaches. To this end, the current format for the initiative is a series of workgroups focused on gel separation, sample processing, mass spectrometry, and molecular interactions, which in turn has produced reporting standards on the overall MIAPE framework, study design and sample generation, statistical analysis of data, gel electrophoresis, gel image informatics, chromatography, capillary electrophoresis, sample processing, mass spectrometry, mass spectrometry informatics, and molecular interactions.

The Proteomic Standards Initiative Mass Spectrometry Standards (PSI-MSS) working group has defined community-accepted data formats for reporting proteomic experiments as well as developing a controlled vocabulary to assist in data exchange and storage. Their work led to the development of the mzData format standard for reporting mass spectrometry data. This has been so successful that all mass spectrometry vendors have embraced this as an initiative and will now allow the export of data in an mzData-compliant format. However, this is now being subsumed into the mzML format, which also includes another parallel development referred to as mzXML, developed by the Seattle Proteome Center at the Institute for Systems Biology in Seattle. Also, ongoing is a description of transition experiments in mass spectrometry to report selective and multiple reaction monitoring (SRM and MRM, respectively) based experiments referred to as TraML.

In addition to PSI-MSS, the sample processing working group deals with all the guidelines, data exchange formats, and controlled vocabularies for all the separation techniques not considered under classical gel electrophoresis (which has its own working group) in addition to other commonly used sample-processing techniques, such as tagging proteins, and storage of samples. Of particular relevance to this article, the group also oversees the area of column chromatography which indeed was conceived to be consistent not just with liquid chromatography but also with gas chromatography so that standardization in the proteomic field could be similarly expanded to neighboring fields such as metabolomics.

Just as in the field of microarray experiments, developments in data standardization have also produced developments in databases. The PRoteomics IDentifications (PRIDE) database is a centralized public repository for proteomic data. The aim of the database is to provide the

proteomic community with the ability to store data on protein and peptide expression, as well as the associated data to describe the identifications. More recently, it has expanded to also capture information concerning post-translational modifications. It was developed through a collaboration between EMBL-EBI and Ghent University, Belgium, and its development has since been closely linked with the HUPO-PSI initiative.

The Metabolomics Standards Initiative (MSI)

When considering the developments in microarray and proteomic fields, it is perhaps unusual that the developments in metabolomics first came about through database design and then standardized descriptions followed. However, this reflects the fact that there has been a great need in both spectroscopy and spectrometry fields to identify unknown compounds prior to the functional genomic revolution of the late 1990s. Thus, prior to the coining of the words metabolomics and metabonomics, there were already databases for recording chemical shift and coupling patterns of small molecules, largely to assist chemists and biochemists in mixture analysis. There are now several online databases that allow deposition of NMR experiment results, such as NMRShiftDB for organic structures (<http://www.nmrshiftdb.org/>) and BioMagResBank (BMRB) (<http://www.bmrwisc.edu/>) initially for NMR-determined protein structures, but then extended to small organic molecules and now encompassing metabolomic data too. These databases are mainly built to facilitate deposition of NMR spectra together with various amounts of associated metadata. In addition, data exchange formats for NMR datasets are available from both the Collaborative Computing Project for NMR (CCPN) that offers a data model for macromolecular NMR and related areas, and JCAMP-DX. Also, a more general XML (eXtensible Markup Language) (<http://www.w3.org/TR/xml11>) format for analytical chemistry, which is currently in prerelease form, has been developed by the AnIML (Analytical Information Markup Language) (<http://animl.sourceforge.net/>) initiative.

However, since the development of metabolomics/metabonomics as a functional genomic tool, the acquisition of data by both NMR spectroscopy and mass spectrometry-based approaches has markedly increased in volume, leading to the creation of a number of databases, both public and private.

The pharmaceutical industry has demonstrated a great deal of interest in this technology as part of the drug safety assessment process. The Consortium for Metabonomic Toxicology (COMET), consisting of Imperial College London, Bristol-Myers Squibb, Eli Lilly

and Company, Hoffman-LaRoche, NovoNordisk and Pfizer Inc., investigated ~150 model toxins and treatments, mostly of the liver and kidney, through NMR-based analysis of urinary, plasma, and tissue metabolites over a three-year period. To achieve this, it was first necessary to determine how reproducible such a database would be in terms of both the collection of samples and the resultant NMR analysis. Examining hydrazine toxicity in the rat, it was found that the variation in NMR-based metabolomics as a result of conducting a study across seven different laboratories was minor in comparison to the variation associated with the toxic lesion. This demonstrated that datasets could be exchanged between different groups, especially if SOPs were already in place to facilitate the generation of cross-laboratory databases.

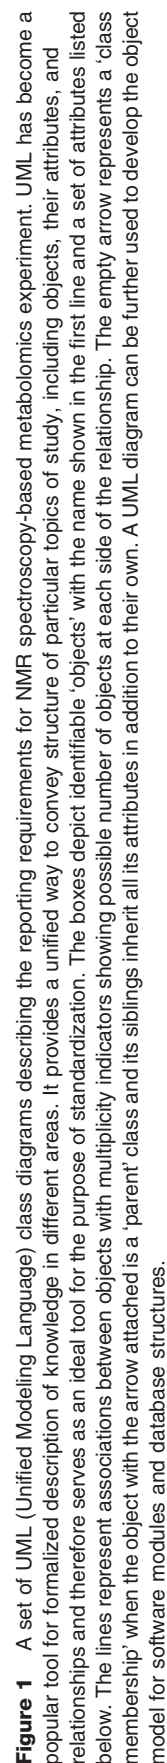

In addition *in vivo* NMR databases have been produced where automated pattern recognition tools have been used to aid radiologists categorize magnetic resonance spectroscopy (MRS) data of brain tumors according to histological type and grade. One powerful application of an NMR database for studying metabolism *in vivo* is the INTERPRET database, developed as part of an academic collaboration between a number of European hospitals. An automated pattern-recognition approach has been implemented to help radiologists categorize MRS data of brain tumors according to histological type and grade. It can successfully distinguish meningiomas, low-grade astrocytomas, and 'aggressive tumors' (glioblastomas and metastases). This pattern-recognition process was even successful at predicting tumor types using data acquired at another site using a different MRI instrument, indicating pattern-recognition algorithms are less sensitive to acquisition parameters than had been expected. These applications indicate that central databases for metabolomic data, using information from several different sites, are a realistic possibility and will provide useful resources for the wider research community.

As the amount of metabolomic data grows on the Internet, the community has been responding by developing a number of standard initiatives for reporting experiments. The context-dependent nature of information in metabolomics studies adds complexity to the problem of systematically describing the experiment results. The presence of many potential, and not always obvious, sources of experimental variation makes it difficult to extract the relevant biological information contained within metabolomic data and requires a detailed experiment description. This presents a challenge to the dissemination, interpretation, reviewing, and comparison of these experimental results. Moreover, since several different NMR and mass spectrometry-based approaches are used in metabolomics, a comprehensive and metadata-rich description plays a crucial role in facilitating adequate cross-comparison and assessment of results.

In the field of plant metabolomics, minimum information about a metabolomics experiment (MIAMET) and architecture for metabolomics (ArMet) were developed with the intention they could be extended to the wider metabolomics community. However, being focused largely on mass spectrometry-based approaches, it did not model well the NMR community based projects. The Standardized Metabonomics Reporting Structures (SMRS) group was initiated and developed at a similar time by a consortium of academics, instrument manufacturers, and industry end-user scientists with a wide range of applications including pharmaceuticals, plant science, food science, and research contract organizations. There has also been one detailed study of the scheme required to describe an NMR spectroscopy experiment for metabolomics produced by the ABC consortium (Aberystwyth, Birmingham, and Cambridge universities, UK), which describes in detail how an NMR experiment should be described to fully define all the parameters used in both one-dimensional and multi-dimensional experiments (Figure 1).

These parallel developments served as inputs to the MSI that is orchestrated by the Metabolomics Society (<http://www.metabolomicssociety.org/mstandards.html>). The MSI is split into five working groups consisting of biological context metadata (description of the origin of material in terms of description of the animal, plant, or microbial experiments performed), chemical analysis, data processing, ontology, and exchange format workgroups. These workgroups were set up to reflect the workflow in a typical metabolomics experiment and pass through study design, sample workup, data acquisition, processing, and export of data to other functional genomic databases. The work of both the ontology and exchange format groups was carried out in collaboration with other community initiatives, including HUPO-PSI, MGED, and FuGO/FUGE (see the following text).

The aim of the Chemical Analysis Working Group (CAWG) 'is to identify, develop, and disseminate a consensus description for the best chemical analysis practices related to all aspects of metabolomics.' However, it was emphasized during this process that the group wanted to describe a metabolomics experiment rather than prescribe how to carry out the analysis. Thus, the group set out to describe the minimum amount of information required to describe the analytical analysis of a biological samples for metabolomics, and included terminology to describe chromatography, mass spectrometry, NMR spectroscopy, IR spectroscopy, and other related techniques. The document they produced to act as a guide to the minimum information required for describing chemical analysis began with a detailed analysis of the various extraction procedures used to prepare a sample prior to analytical analysis. This was followed by a description of any chromatography that might be used, and

although largely focused on mass spectrometry-based approaches, was equally relevant to others using LC-NMR, as well as diode and Coulombic arrays, or even the use of solid phase extraction techniques rather than HPLC-based methods. Descriptions of the chromatography unit and columns were included alongside the actual chromatography parameters used and whether this was carried out in conjunction with prior derivatization. A detailed description was then required of the use of the analytical device with a strong focus on techniques based on mass spectrometry, NMR spectroscopy and stable isotope analyses for flux determination.

Unlike other standardization initiatives, the CAWG of the MSI also felt it necessary to include a description of both quality control measures (e.g., the frequency at which known standards were run and what internal standards were used in a given study) and how metabolite identification was performed. Indeed, the document even includes a description of how known unknowns should be described! It was suggested that for NMR spectroscopy the exact chemical shift and multiplicity of at least one nucleus in the metabolite should be part of the unknown designation (e.g., triplet at chemical shift 1.16 ppm). For MS, the retention time and prominent ions in the mass spectrum should be reported along with MS-MS data if available.

Future Developments in Global Standardization

As mentioned both the MSI and MIAPE initiatives developed their chemical analysis work packages with a view of wider community interactions between functional genomic approaches. This as much reflected the involvement of similar people in the initiatives as much as it involved similar technologies. There was particular overlap in the areas of chromatography and mass spectrometry. This fact and the rise of systems biology has led to an initiative to combine all the standards in reporting functional genomic experiments. The Functional Genomics Experiment project (FuGE; <http://fuge.sourceforge.net/index.php>) sets out to develop an object model (FuGE-OM) and a markup language (FuGE-ML) to describe the vast array of functional genomic experiments

that can be performed. The aim is to provide a model of common components across functional genomic studies, including sample generation, data acquisition, and data processing to allow the development of modules that can interconnect between approaches. In this way it is hoped that FuGE will capture the complete laboratory workflow in a systems biology experiment, which might consist of a number of different functional genomic tools.

In an effort to track the development of standardization initiatives across the community, the MIBBI project was formed (<http://www.mibbi.org/>). This aims to maintain a web-based, freely accessible resource for checklists to ultimately aid in the development of a universal checklist resource for the whole bioscience community.

Symbols

ΔA	differential absorbance
A_L	absorbance from left-circularly polarized light
A_R	absorbance from right-circularly polarized light
$[H_T]$	total concentration of a host
$[L_T]$	total concentration of a ligand
$[H]$	concentration of a bound host
$[L]$	concentration of a bound ligand
$[HL]$	concentration of a bound host–ligand complex
K	equilibrium binding constant
$\Delta \epsilon$	differential molar extinction coefficient
ϵ	molar extinction coefficient
c	concentration in mol l ⁻¹
l	cuvette pathlength in cm

Abbreviations

CD	Circular dichroism (CD)
ECD	electronic CD
HL	host–ligand complex
ITC	isothermal titration calorimetry
OR	optical rotation
ORD	optical rotatory dispersion
ROA	Raman optical activity
VCD	vibrational CD

Fluorescence relies on the presence of fluorophores with sufficient intrinsic fluorescence. The majority of proteins contain useful fluorophores such as tryptophan and tyrosine amino acid residues that can be used to probe binding interactions. However, their intrinsic fluorescence is rather modest. The introduction of more sensitive fluorophore probes by chemical tagging might induce positive or negative results by promoting or hindering the binding interactions. This is encountered in high-throughput drug screening where the reliability of positive and negative results to select lead compounds cannot be dismissed. The open question is how good is the screening test, in other words how many positive results are biased by the artificial binding promoted by the tagged fluorophore and how many bindings are missed, that is, negative results, induced by the steric hindrance of the tag moiety?

CD spectroscopy has none of these limitations; however, the setting of the optimal instrumental and experimental parameters to obtain the necessary good signal-to-noise CD spectra is less user-friendly than the other techniques. The analysis of the data is not yet available as a comprehensive software package like for ITC.

The ‘golden’ rules on how to carry out good ligand titrations and what protein–ligand concentrations to choose in order to study binding interactions of biologically important molecules by CD spectroscopy are described in here.

Introduction

The most important and frequently used techniques to study, monitor, characterize, and analyze binding interactions of nonimmobilized molecules in solution are isothermal titration calorimetry (ITC), fluorescence, and circular dichroism (CD). For a detailed and thorough study of complex biosystems, one technique is seldom enough. This is also because each technique has its own limitations.

ITC requires a significant amount of sample, particularly, when the heat released upon binding is rather small. For more complex systems where multiequilibria may exist, for instance, intra- and intermolecular interactions (association), the binding can be very difficult to be determined correctly particularly when the ligand and the host are in different solvents due to solubility problems.

Optical Activity

A chiral molecule is not superimposable on its mirror image and as a consequence it shows optical activity in the form of optical rotation (OR), optical rotatory dispersion (ORD), CD, and Raman optical activity (ROA).

Linearly polarized light can be seen as the sum of two circularly polarized lights in opposite directions, one left and one right.

OR is the difference in speed between the propagation of left- and right-circularly polarized lights that pass through a chiral medium. With no light absorption from the sample, the result is the rotation of the plane of linearly polarized light. ORD is the change of OR as a function of wavelength.

CD is a small difference in the absorption between left- and right-circularly polarized lights of a chiral

Figure 1 CD spectra of the titration of proline-rich peptides P2 (primary sequence PPPLPPKPKF) and P3 (PPPNSPRPGPPP) into aqueous GST-SH3 protein domain (60 μM). In the 280–330 nm region, both peptides have no CD due to the lack of Trp and Tyr aromatic residues. GST-SH3 domain shows a CD signal that is changing upon addition of P2 but not for P3. This is unambiguously indicative of binding interactions between GST-SH3 domain and P2 peptide. The K_d was determined by fitting the plot ΔA intensity at 291 nm versus peptide concentration using a nonlinear regression analysis from the software program Origin. In this figure as well as in the other figures, CD spectra were measured using a Jasco J720

Figure 2 CD spectra of the titration of p50 protein into hsp90 protein (96 μM). As both proteins have plenty of aromatic residues, the CD arises from both proteins. The 1:1 stoichiometry of the titration was revealed by the plot ΔA intensity at 293 nm versus molar fraction of $[\text{p50}]/([\text{p50}] + [\text{hsp90}])$.

spectropolarimeter purged with nitrogen gas. Multiscan mode was used to improve the signal-to-noise ratio. This varies from system to system but either four or nine scans with the highest scan speed are normally used. With the J720 a scan speed of 20 nm min^{-1} , time constant of 4 s, and bandwidth of 2 nm were used. Using different instruments and of different brands, it is important to find the optimum parameters to obtain the best signal-to-noise ratio spectra. A special 1 cm cylindrical cell (Hellma, Müllheim, Germany) with a volume of 520 ml was used to carry out the CD titrations. Positive display pipettes of 2–20 and 20–200 ml tips (Finnpipette) were used to directly add aliquots of ligand protein or peptide to the host protein placed in the cuvette cell of suprasil material. The concentration was determined by weighing using a microbalance with $\pm 1 \text{ mg}$ sensitivity (Mettler Toledo, Columbus, OH). The determination of accurate protein concentration is not trivial. Special care should be taken to ensure that good accuracy is achieved because any inaccuracy will be reflected in the determination of the K_d as well.

molecule. Electronic CD (ECD) is generated by molecules with chromophores absorbing in the UV and visible spectral regions, whereas vibrational CD (VCD) is generated in the IR spectral region.

ROA is a small difference in Raman intensity between right- and left-circularly polarized lights or scattered circularly polarized light of a chiral molecule.

Both CD and ROA arise from the absolute configuration (the chirality, or handedness) and the molecular structure (the conformation).

The absolute configuration of small, relatively rigid molecules with up to 30 atoms can now be determined, thanks to the revolutionary developments of density functional theory methods for the calculation of ECD, VCD, and ROA spectra. Rather demanding calculations including solvent interactions for larger and more flexible molecules (peptides) with about 120 atoms have been recently achieved. It is conceivable that in a not distant future, maybe in the next decade thanks to less computationally expensive calculations, small proteins will be

tackled leading the way to even larger protein systems. The implication is that the 3D structure of proteins in solution could be determined one day with sufficient resolution from observed and calculated ECD, VCD, and ROA spectra from a pool of conformations sampled from quantum mechanical molecular dynamics.

For biologically important molecules, such as proteins, nucleic acids, carbohydrates, and lipids, CD spectroscopy is the technique of choice to investigate and characterize structural molecular behavior in solution.

Figure 3 Difference CD spectra of the titration of p50 protein into hsp90 protein. As both proteins contribute to the CD spectrum, the K_d is determined by subtracting from the CD spectra of hsp90 with p50 at different molar ratios the equivalent CD contribution of p50 alone. In this manner the plot ΔA versus ligand concentration reaches saturation, otherwise it will look like the stoichiometry plot of **Figure 2**.

Figure 4 Difference CD spectra of the titration of Sba1 into preformed hsp90 + AMP-PNP (1:2) complex (30 μ M). The 2:1 stoichiometry indicates that one molecule of p23 protein binds to an hsp90 dimer.

For proteins, made of L-amino acid residues, CD is advantageously used to monitor, characterize, and estimate the protein secondary structure in the far-UV region (180–250 nm). The local tertiary structure of the aromatic amino acid residues observed in the near-UV region (250–330 nm) can be used for quality control as it often reveals subtle changes from batch to batch often not mirrored in the far-UV region.

Another important use of CD is to probe qualitatively and quantitatively binding interactions in a solution of biomolecules without the need of immobilizing and labeling them.

The application of CD spectroscopy to determine binding interactions is not as diffused as it should be. The main task of this review is to facilitate and improve this diffusion.

Binding Interactions of Nonimmobilized and Nonlabeled Biomolecules in Solution by CD Spectroscopy

For a host–ligand (HL) complex formed from the interaction between the host (H) and the ligand (L), the apparent dissociation constant $K_d = 1/K$ is determined by analyzing the CD data expressed in $\Delta A = (A_L - A_R)$ using a nonlinear regression analysis. At equilibrium, for a single binding site, eqn [1] used to determine the K_d has been derived from $\Delta A = \Delta A_{HL} + \Delta A_H + \Delta A_L$, $[H_T] = [H] + [HL]$, $[L_T] = [L] + [HL]$, and Beer's law $A = \epsilon c l$ with $l = 1$ cm:

$$\Delta A = (\Delta \epsilon_H - \Delta \epsilon_{HL}) \frac{(K[H_T] + K[L_T] + 1) - ((K[H_T] + K[L_T] + 1)^2 - 4KK[H_T][L_T])^{-1/2}}{2K} + \Delta \epsilon_H[H_T] \quad [1]$$

Usually CD titration is conducted in a stepwise manner, adding small aliquots of 3–5 μ l of ligand stock solution directly into a cuvette of appropriate pathlength that contains a known volume of the host component to be titrated. For measurements in the 190–250 nm spectral region the optimum UV absorption in a 0.05 cm pathlength is approximately 0.8, whereas in the 250–350 nm region the absorption in a 1 cm pathlength is approximately 1–1.4. To add 1 molar equivalent of ligand in a 20 μ l volume, the concentration of the stock solution to be prepared is approximately 50-fold that of the concentration of the host component.

The quadratic equation to calculate K_d has been derived from a two-component system where only one component has intrinsic CD (Figure 1). However, when both host and ligand components possess intrinsic CD

(Figure 2), eqn [1] can be converted back into one active component system using difference CD spectra. This can be obtained by subtracting from each observed CD spectrum of the HL (1: n) mixture the equivalent CD contribution of the ligand of n molar ratio (Figure 3). To obtain high accuracy, it is important to terminate the titration upon reaching saturation or as close as possible. As a rule of thumb, a 2–3 molar excess of ligand is required for stronger bindings, whereas, 4–6 molar excess or even higher, is needed for weaker bindings.

Important information that can be obtained with the K_d is the stoichiometry of the binding. This can be calculated by plotting the intensity of differential CD or CD at single wavelength versus ligand molar fraction (Figures 2 and 4).

The assessment of the experimental parameters, to be used for the binding interaction study, is essential to obtain meaningful and, above all, accurate results.

What is the right concentration for the host component to be titrated by the ligand? To obtain a curve fitting like a Michaelis–Menten type of saturation curve illustrated in Figure 1, the concentration is approximately 50–100-fold that of the dissociation constant $K_d = 1/K$. For example, a tight binding affinity with K_d in the 10–20 nM range requires a host solution of approximately 5–10 μ M concentration whereas a medium affinity with K_d in the 1–10 μ M range requires a host solution of 50–100 μ M concentration. If the host concentration is less than 100 K_d , the fitting curve is of parabolic shape (Figure 5). By CD spectroscopy, the range of the K_d of

binding interactions that can be successfully determined spans from millimolar to nanomolar.

In Figure 6 are illustrated several simulated fitting curves using K_d values from 1 nM to 10 μ M. The fitted curves showing a very sharp edge cannot be discriminated very well whereas the more parabolic one can. The discrimination between 1 and 10 nM K_d curves (Figure 6) can be achieved by repeating the titration with a more dilute total host concentration. The dilution means that to measure a good signal-to-noise spectrum a longer pathlength has to be used. Ideally the dilution factor is used to determine the cell pathlength. In general, eqn [1] very well fits binding interactions of one single binding site. Failure to fit the experimental data due to wrong concentration components is nevertheless revealing. For instance, host association might obscure the binding site.

Figure 5 CD titration of a sugar ligand into lysozyme at different concentrations. The sugar moiety is transparent in the near-UV region; therefore, there is no need to transform the CD data into different CD data like for **Figures 2** and **3**. As the affinity is concentration independent, the K_d remains the same but the fitting is no longer of Michaelis–Menten type using the highest host concentration. With lower host concentration the curve becomes parabolic and higher ligand excess is required to accurately fit the binding curve.

In this case there is a struggle to fit the slope of the first experimental data points reaching 1:1 molar ratio and the data can be fitted only by reducing the total host concentration in the regression analysis. Only the fraction of available binding site can interact with the equivalent ligand concentration. The number of binding sites, one or more, can be verified by an accurate determination of the stoichiometry, which requires an accurate determination of the host and ligand concentrations. Obviously for more than one binding site, eqn [1] cannot be used qualitatively to determine the K_d .

Indications that more than one equilibrium might be present in the titration can be inferred when, at high ligand molar excesses, the experimental CD data cannot be fitted and light scattering at longer wavelengths is observed. The host or ligand components might be unstable in their unbound forms and might precipitate once saturation is reached. The signature for this case is the clear lack of saturation plateau (**Figure 7**). The titration

Figure 6 CD spectra calculated using eqn [1] of the nonlinear regression analysis with in the software program Origin. The fitted curves have been simulated using different values of $K_d = 1/K$ to show how the plotted curves change in terms of profile. In this example the initial total host concentration was $10 \mu\text{M}$. The black solid squares are the experimental CD data point at 286 nm while the simulated CD curves have been calculated with different K_d : 1 nM, 10 nM, 100 nM, $1 \mu\text{M}$, $2 \mu\text{M}$, $5 \mu\text{M}$, and $10 \mu\text{M}$. Note that the simulated CD spectra using 1 nM and 10 nM K_d cannot be discriminated as they superimposed one another.

Figure 7 Analysis of Hsp90–p50 interactions by near-UV CD. The ligand p50 has a weaker tendency to interact with itself than to Hsp90; hence, the titration will show two events. The first is the formation of the Hsp90–p50 complex followed by p50 association for greater 1:1 molar excess concentration. The fitting can be still carried out and, assuming the plateau occurred at approximately 1:1 molar ratio concentration, it will give an apparent K_d of $2.5 \mu\text{M}$. It is important to note that other spectroscopic techniques will only at best give the overall picture of both events without allowing an educated guess of the strengths of the interactions.

might be repeated in different buffer or solvent conditions to solve or improve the solubility issues hence allowing a more accurate K_d determination.

Once the host concentration has been chosen, the choice of the pathlength is dictated by the molar extinction coefficient of the chromophore. For protein–protein

or protein–peptide titrations, the total concentration reached upon saturation cannot exceed UV absorption of 0.8 in the 190–260 nm (backbone region) and 1.2–1.4 in the 250–340 nm spectral region (aromatic residues and disulfide bond) otherwise signal cutoff is reached. From Beer's law, the calculation of the cell pathlength requires the knowledge of the concentration, the absorption, and the molar extinction coefficient. For proteins and peptides, the molar extinction coefficient can be approximately calculated from the number of Trp, Tyr, Phe amino acid residues, and S–S bonds present in the primary sequence. A set of UV cuvette cells of different pathlength (0.001, 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1, 2, and 5 cm) will allow the right choice of pathlength, longer for dilute and shorter for concentrated solutions, in order to obtain CD measurements with the highest signal-to-noise ratio.

For small intrinsic CD signals, the choice of instrumental parameters such as integration time or time constant, multiscan acquisition, increased photon flux of the light source needs to be optimized for each titration in order to improve the signal-to-noise ratio that is paramount to determine as accurately as possible the binding affinity of molecular interactions.

Introduction

The term medical imaging encompasses several different modalities which use a wide range of physics phenomena to provide information about the anatomy, physiology, and other characteristics of living systems. The resulting images depend on the physics of data acquisition and image creation and, in general, may be classified into two categories. Methods that show structural details or anatomy are usually sensitive to some physical features of the imaged object. For example, computed tomography (CT) measures attenuation of X-rays passing through the body, magnetic resonance imaging (MRI) the intensity of magnetic resonance signals, and ultrasonography (US) the reflection and transmission of ultrasound waves. However, investigation of organ function, physiology, and/or metabolic processes requires, in most cases, the use of special contrast agents that must be introduced into the studied object.

In this respect, NM single-photon imaging is an inherently functional technique. It uses radiopharmaceuticals (also called radiotracers), biologically active substances which have their molecules tagged with radioactive isotopes, to provide information about distribution of these substances in the body. As the injected radiotracer is selectively absorbed (uptaken) and metabolized in different organs and areas of the body, the measurements of its radioactive emissions allow doctors to investigate the normal and altered function of these organs. Some of the most common medical

applications of single-photon imaging include myocardial perfusion studies which are used in the diagnosis of coronary arterial disease (CAD), lung ventilation, and perfusion studies of pulmonary emboli, bone scans to search for abnormal growths or inflammation, investigations of renal function, and detection and monitoring of cancerous lesions.

Recently, NM's role is increasingly recognized in the bioresearch community as one of the best molecular imaging (MI) techniques because it is able to localize molecular receptor sites, study biological markers expressed by diseased cells, and image the presence and extent of specific disease processes.

A further advantage of NM is its widespread availability and moderate cost as compared to other modalities. Unfortunately, NM imaging, although very sensitive, suffers from relatively poor resolution and often shows few or no anatomical details. For this reason, hybrid cameras, combining single-photon emission computed tomography (SPECT) and CT systems, enjoy increasing popularity in clinical departments. These systems generate functional information from images of radiotracer distribution reconstructed from NM acquisitions, together with the detailed anatomical information obtained from CT images acquired during the same study. **Figure 1** shows an example of SPECT-CT tumor study. It has been

Figure 1 A case of a metastatic tumor imaged with ^{111}In -octreotide. Although tumor increased uptake clearly shows in SPECT images, only a combination of SPECT and CT displays provides functional and anatomical information allowing for accurate localization of all tumor sites.

demonstrated that this approach significantly improves the accuracy of diagnosis. Additionally, CT maps are routinely used for correcting SPECT data for attenuation effects that degrade image quality.

The discussion of principles of single-photon imaging is presented in a separate section; here the focus is on some of the most important clinical applications and NM's role in molecular research.

Clinical Imaging Protocols

The main objective of routine clinical NM studies is to provide answers to diagnostic questions and, depending on the clinical situation, the data are collected using one of many different acquisition protocols. The protocol determines how the data are processed, analyzed, and displayed. In general, clinical protocols for single-photon emission studies may be classified as follows:

1. For planar imaging the camera head (detector) is positioned next to the investigated organ, such as heart or lungs, and the data are collected in this one position for several minutes resulting in a 2-D image of activity distribution. Planar images, however, suffer from poor contrast because photons coming from different layers in the body overlap and contributions from different organs cannot be separated.
2. In a SPECT study the camera rotates around the patient acquiring multiple projections at different angles. A whole series of these 2-D projections is subsequently reconstructed into a single tomographic image which corresponds to a 3-D map of radiotracer distribution in the body.
3. In a whole-body (WB) planar acquisition two camera heads move slowly along the patient creating 2-D anterior and posterior images of the body. Alternatively, a series of two or three SPECT images acquired over different regions of the patient may be combined into a single 3-D composite image showing radiotracer distribution in all organs of the body.
4. Dynamic studies aim at diagnostic investigation of different time-dependent body functions. By imaging the flow of radiotracer through an organ or by measuring changes of activity distribution in this organ, functional dynamic images are obtained. Usually, dynamic studies correspond to a series of planar images that are acquired over time.
5. Finally, gated cardiac studies are done by synchronizing photon acquisition with an ECG signal. This allows for creation of a series of 3-D images, each corresponding to a particular phase of a beating heart. These images may be viewed as a movie showing movement of the myocardial walls.
6. Recently, studies corrected for breathing motion became possible. In these studies data acquisition is

gated by the output signal from a monitoring device which tracks patient breathing movements. Then, the resulting series of images are aligned with each other and coregistered creating composite images without blur, thus having improved resolution and no artifacts.

Radiotracers

Proper selection of a radiopharmaceutical is essential for the success of an NM study. Each radiopharmaceutical has two components: a biologically active molecule and a radioactive isotope which is attached to this molecule. First, the tracer molecule must be selected, so that when it is introduced into the patient it will follow a biodistribution path which is relevant for a given diagnostic question. Then, using a chemical reaction, one of the atoms in the molecule is replaced by a radioactive isotope. There are several conditions which the radioisotope must fulfill some of which are imposed by the limitations of the current imaging systems. The energy of emitted photons must be in the range 70–400 keV, high enough so that a sufficient number of photons exit the patient body without absorption and, at the same time, are stopped and recorded by the detector. The isotope must also be inexpensive, relatively easy to produce, and must attach to the pharmaceutical molecule. Its half-life must allow enough time for production and radiochemistry. However, too long a half-life increases the radiation dose and is thus harmful to the patient. The most commonly used radioisotope is technetium-99m (^{99m}Tc), with a 6 h half-life emitting 140 keV photons.

As mentioned, each pharmaceutical is designed to provide information on a specific biological process. **Table 1** lists some of the most popular radiotracers that are used in single-photon imaging together with their applications.

Clinical Single-Photon Imaging Studies

On a cellular level, disease often begins with altered cell function which, at a later stage, may lead to distortions in physiology or metabolism in the surrounding tissues or the entire organ. Thanks to its great sensitivity, NM is able to detect these functional effects early, usually well before any structural or morphological changes occur and become visible in CT, MRI, or US. For this reason, NM clinical applications include a wide range of studies, in spite of the fact that the images display relatively poor resolution and high noise levels. This is because dose considerations allow only a very small amount of radioisotope to be injected in diagnostic studies. Clinical applications of NM include imaging studies of almost any organ or part of the body. Here only some examples of the most important applications are discussed.

Table 1 Examples of the most popular radioisotopes used in clinical single-photon emission studies

Isotope	Half-life	Main γ -emissions (keV)	Photon abundances	Examples of clinical applications
^{99m}Tc	6 h	140	89%	Brain, heart, liver, lungs, bones, cancer, kidneys, thyroid
^{67}Ga	3.26 days	93	38%	Abdominal infection, lymphoma, cancer imaging
		185	21%	
		300	17%

Cardiac Imaging

CAD is one of the leading causes of death. Arteriosclerosis, or hardening of arteries, is the major cause of CAD, usually involving inflammation of cells lining blood vessels. Tissue degradation and formation of plaque leads to blocking of the arteries which supply blood to the heart muscle, and danger of myocardial ischemia (restricted blood supply) and/or infarction (tissue necrosis caused by inadequate blood perfusion) results. Although X-ray angiography provides structural information about anatomy of the heart and the coronary blood system, and recently introduced ultrafast CT scanners are able to measure miniscule calcifications in blood vessels, NM imaging remains the most important noninvasive diagnostic method for assessment of physiologic and hemodynamic extent of the CAD and other heart diseases.

In general, nuclear cardiology procedures amount to approximately 30–50% of all studies performed in a busy clinical department. These studies are used to assess different aspects of cardiac performance, evaluate blood perfusion, and measure myocardial viability and metabolism. The list of cardiac studies includes myocardial perfusion imaging (MPI), measurement of tracer transit through the central circulation system (first pass study), and examination of the pumping chambers of the heart using gated cardiac blood pool imaging (multiple gated acquisition – MUGA study).

The MPI studies are usually performed in two stages. First, after a small ^{99m}Tc -sestamibi injection, the first study is performed. By recording emission of this radiotracer as it circulates in the blood, perfusion of the heart muscle is measured in a normal, rested state. Then, a few hours later, when the radioactive material is almost completely eliminated from the blood stream, a stress study is performed. The patient is asked to exercise on a treadmill or a pharmacologic stress agent is administered. At the maximum exercise, when myocardial oxygen consumption is at its peak level and all normal blood vessels are dilatated, a second injection is performed. Since CAD causes coronary stenosis

Figure 2 Rest and stress images of the short axis of a heart with clearly visible perfusion defect in the stress part (the heart has been reorientated to have its main axis perpendicular to the page).

(narrowing of blood vessels) and prevents increase of blood flow, the arteries which are stenotic will not expand. Resulting blood flow heterogeneity will cause the parts of myocardium which are supplied by stenotic arteries to be less perfused. Since radiotracer concentration is proportional to blood flow, by comparing images obtained during rest and stress, an NM physician can diagnose and assess the extent and severity of CAD. An infarcted area (necrotic tissue) demonstrates reduced perfusion in both stress and rest studies but reversible ischemia demonstrates decreased uptake only in the stress scans. Additionally, by acquiring some or all of the tomographic data as gated with the ECG signal, four-dimensional movies of the myocardium may be created, allowing for evaluation of heart motion and myocardial wall thickening. **Figure 2** presents rest and stress images of the short axis of a heart with clearly visible perfusion defect in the stress part. **Figure 3** shows an example of a typical screen capture of a rest and stress study. The bull's-eye representation is often used in the analysis of cardiac images; it shows all segments of the myocardium displayed side by side in the form of a disk.

Figure 3 An example of a screen capture of a rest–stress MPI study. A bull’s-eye representation shows all segments of the myocardium displayed side by side in the form of a disk.

Bone Scans

A number of bone and joint disorders result in functional changes in the skeletal system and bone imaging provides a display of such skeletal activity. Bone imaging is usually performed using phosphate and diphosphonate complexes labeled with ^{99m}Tc , with methylene diphosphonate (^{99m}Tc -MDP) being the most commonly used. As the tracer circulates in the blood, it gets preferentially deposited in areas of bone infection and inflammation, following, for example, a fracture or trauma. Bone imaging also detects the presence of metastatic bone disease before it becomes visible in X-rays or CT scans. Serial bone scans are an accurate and objective method to monitor the activity of skeletal disease during treatment, for example, to assess effectiveness of chemotherapy in patients with known metastatic bone involvement. **Figure 4** shows an example of a WB planar bone scan of a patient with multiple metastases.

To check for all potential sites of disease, bone scans are usually performed as WB studies. Although tomographic images have better contrast than planar images, WB SPECT requires multiple SPECT acquisitions which take much longer than a single WB planar study.

Therefore most bone scans are done using a planar mode. In a planar WB scan a dual head camera moves slowly along (below and above) the patient who is lying on a scanning bed. Sometimes, to assist in further diagnosis, an additional tomographic SPECT scan is performed over the area with the identified disease.

More recently, with the advent of a new generation of iterative reconstruction algorithms, WB SPECT scans are gaining popularity. Images obtained from reconstructions with resolution recovery correction show much improved quality, better resolution, and lower noise than those reconstructed using the standard filtered backprojection method. Their use in half-time acquisitions has been advocated with the claim that the resulting images are diagnostically equivalent to full-time images reconstructed using standard methods. If validated, this new approach will allow for WB SPECT imaging to replace WB planar studies.

Lung Scans

There are two types of lung imaging studies that use different methods of radiotracer administration and are

Figure 4 An example of a WB planar bone scan of a patient showing multiple metastases. (anterior and posterior).

sensitive to different aspects of pulmonary physiology. In the first type, lung blood perfusion studies, a ^{99m}Tc -macroaggregated albumin is used. Injected intravenously, it is taken up by the pulmonary arterioles providing a noninvasive method for evaluation of pulmonary arterial blood flow. A second type, lung ventilation studies, uses inert gases (such as ^{127}Xe , ^{133}Xe , or ^{81m}Kr), or nebulized aerosols (^{99m}Tc -DTPA) and sulfur colloid. In ventilation studies, the patient is usually asked to take one deep breath of the radioactive gas while sitting in front of the camera. The particle sizes must be small enough to reach the alveoli showing different types of lung obstruction. In many clinical situations, both perfusion and ventilation studies are performed as they provide complementary information, which is often necessary for a comprehensive evaluation of pulmonary function (Figure 5). Common indications for a lung scan range from diagnosis of pulmonary embolism, lung carcinoma, bronchial obstruction, and lung pathology.

Imaging of Kidneys and Renal Function

Good kidney function is vital for human health. The two kidneys together receive about 20% of cardiac output as they clear soluble waste products from the body. The primary method for clearing is by filtration at the level of the glomerulus, which cumulatively is termed the

Figure 5 An example of a series of images showing different angular views from a lung perfusion and ventilation study.

glomerular filtration rate (GFR). Chronic renal disease affects one in twenty individuals, with the incidence rising because of multiple factors, such as advancing population age, increased prevalence of diabetes and hypertension.

NM plays a central role in evaluating renal function as it provides a number of very sensitive functional imaging

methods allowing for evaluation of relative renal blood flow, GFR, tubular function and urinary excretion. Available radiopharmaceuticals often have a mixed pattern of uptake and excretion, and are commonly categorized as either cortical agents, which are primarily taken up and retained by the tubular cells in the renal

Figure 6 An example of a screen capture showing the analysis of a renal dynamic study. Regions of interest drawn on kidneys allow the physician to evaluate renal filtration rate and determine GFR for each kidney.

Figure 7 Multiple transaxial slices from a SPECT brain study.

cortex (^{99m}Tc -glucoheptenate and ^{99m}Tc -DMSA), or clearance agents, which are rapidly extracted from the blood and cleared through the kidneys by glomerular filtration (^{99m}Tc -DTPA) or tubular secretion (^{99m}Tc -MAG3). Both static planar and tomographic static studies are performed in these instances.

The most common procedure currently used in renal imaging is the acquisition of a rapid sequence of planar images over 15–20 min beginning with the injection of a radiotracer. Regions of interest are drawn manually around each kidney, and time activity curves (TACs) are generated. The images, viewed as a movie, as well as TACs, are sometimes sufficient for the nuclear physician to form a diagnosis (e.g., obstruction, assessment of renal artery stenosis, perfusion, and viability). However, determination of a numerical value of GFR is often necessary for complete renal assessment of cortical parenchymal functioning tissue, and the contribution of each

kidney is inferred from the split function. **Figure 6** presents an example of a screen capture showing the analysis of a renal dynamic study.

Other Clinical NM Studies

As mentioned, clinical diagnostic applications of NM involve imaging of almost any part of the body and any organ. Planar and tomographic images of the liver are used in diagnosis of patients with hepatic abscesses and jaundice, and differential diagnosis of abdominal masses and evaluation of liver metastases in patients with known malignancies. Dynamic imaging studies allow physicians to investigate function of the gallbladder and biliary system, diagnose the source and location of gastrointestinal bleeding, and evaluate gastroesophageal reflux. Brain imaging (**Figure 7**) indications range from

Figure 8 An example of small animal (mouse) molecular imaging study. A SPECT bone scan clearly shows small details of a skeleton (a) and SPECT-CT (b) scan with high tumor uptake in a left thigh.

evaluation of different neuropsychiatric disorders, cerebral tumors, and effects of trauma, and assessment of cognitive functions, to studies that are performed to confirm brain death in patients in nonresponsive comas. Further, NM is used to diagnose a wide range of thyroid diseases, image parathyroid and adrenal glands, investigate sources of undetermined infections and inflammations, and even to visualize obstructions of lacrimal ducts. In addition to clinical imaging studies, NM includes several nonimaging diagnostic procedures. Additionally, internal radiotherapy has an increasingly important role to play in oncology, with radiotherapy agents delivering therapeutic doses directly to malignant cells.

Molecular Imaging

Recent advances in molecular biology and genomic research created an enormous demand for accurate, quantitative, and functional *in vivo* information about physiology and metabolism on a molecular, cellular, and organ level. This situation is reflected by growing worldwide excitement and extensive research effort focused on MI techniques, with small animal imaging increasingly recognized as particularly useful in preclinical and translational research.

NM is especially valuable for MI because of its exceptional sensitivity and very low background, as naturally occurring radioactivity in biological systems is usually negligible. This characteristic is particularly useful in investigations where only very small quantities of tracer material can be introduced without changing the attributes of the studied object. Imaging of receptor systems and intracellular processes are good examples of such studies. Successful NM studies usually require about 0.1–10 nmol of radiotracer, as compared to 10 and 100 μ mol of contrast material needed for MRI and CT, respectively.

Small animal NM imaging studies provide excellent *in vivo* models, extremely useful in physiology, pathology, and novel phenotypes investigations. An additional advantage of imaging is that series of tests can be performed longitudinally using the same animals with known pathology. NM methods are able to localize molecular receptor sites, study biological markers expressed by diseased cells, and to image the presence and extent of specific disease processes. The ultimate goal of MI is investigation of specific genes and proteins involved in pathological processes. **Figure 8** presents an example of a SPECT-CT image of a mouse.

Molecular approaches can potentially link diagnosis with treatment and monitor effectiveness of this treatment. For example, in oncology, the same molecule labeled with one isotope can be used to identify and diagnose a tumor; while labeled with another isotope, to carry chemo- or radiotherapy agents to treat it and, in parallel, to monitor the effectiveness of this treatment. In this context, it is expected that monoclonal antibodies and nanoparticle agents will provide a valuable alternative to traditional diagnostic and therapy procedures for oncology and cardiology.

Another obvious benefit of NM imaging comes from a drug discovery and development perspective. Imaging investigations using small animals allow for vigorous testing of new drugs limiting the need for very difficult and costly clinical trials.

Introduction

The scientific study of works of art and the materials that have been used in their creation has received impetus with the development of nondestructive, microsampling analytical techniques and an increasing awareness on the part of art historians, museum conservators, and scientists of the importance of characterization for the attribution of the historical period and genuineness of an artifact. Useful information about ancient technologies and methods used in the construction of works of art is now forthcoming; in particular, spectroscopists are realizing the challenge that is being provided by the analytical characterization of ancient materials.

In this article, the applications of vibrational spectroscopic techniques to art are addressed and examples are taken to illustrate the following:

- identification of pigments, nondestructively, in preserved illuminated manuscripts, paintings, and watercolors;
- characterization of genuine and fake artifacts, for example, ivories;
- rock art and frescoes – effects of environmental and climatic degradation on exposed artwork;
- provision of information about archaeological and historical trade routes from the spectroscopic analysis of dyes, pigments, and resins;
- identification of biomaterials in carved artwork, for example, horn, hoof, and tortoiseshell;
- information of critical importance to art restorers and museum conservation scientists – ill-restored items and the preservation of deteriorating material.

Comparison of Infrared and Raman Spectroscopies

Although both Fourier transform-infrared (FT-IR) and Raman spectroscopies have been applied to the study of art and museum artifacts, it is possible to identify several

indicators that will dictate the preferential use of either technique. IR studies have been reported from a much earlier date than Raman studies; hence there now exists much more comprehensive IR database for pigments and natural or synthetic materials. Specific points also need to be considered relating to the sampling and composition of the specimens being studied. The presence of highly fluorescent coatings or impurities in ancient specimens dictated the use of IR spectroscopy when the alternative was visible excitation for Raman spectroscopic studies; fluorescence often swamped the lower intensity Raman signals from such samples.

However, the smaller scattering intensity of water and hydroxyl groups in the Raman effect, and their strong absorption in the IR, generally favors the use of the Raman technique for the characterization of ancient, hydrated biomaterials such as linens and cottons. In the area of paintings and manuscripts, Raman spectroscopy has had extensive application in recent years because of the accessibility of the low-wavenumber regions of the vibrational spectrum ($<500\text{ cm}^{-1}$), which are vitally important for the characterization of inorganic and mineral pigments. This region is observed only with difficulty in the IR, and then with the use of special instruments with far-IR capability.

The shape and reflectivity of surfaces are also important for specimens that cannot be subjected to mechanical or chemical pretreatment – the taking of small samples by drilling, scraping, or excision is often prohibited. Curved surfaces are notoriously poor for IR examination and specimens are better analyzed after being subjected to a flattening or crushing process. The use of fiber-optic probes for ‘remote’ analysis is now advocated for many IR and Raman applications, and art objects are no exception. However, the interpretation of the spectral data from remote-probe scanning experiments is dependent on accurate subtraction of probe background; this is particularly relevant for features below 1000 cm^{-1} , for example, artists’ pigments. However, the obvious advantage of having the capability of taking the Raman or IR spectrometer into a museum environment for *in situ* examination of an artifact or painting has dictated the construction of several portable units that might well provide a new dimension to these applications.

Finally, the advent of FT-Raman spectroscopy with near-IR excitation from a Nd³⁺/YAG laser at 1064 nm has given a new dimension to art applications, especially for the study of naturally fluorescent biomaterials such as horn, hoof, tortoiseshell, and ivory. Improvements in the generation of Raman spectra and their detection using CCD-visible Raman spectroscopy are now also providing valuable new ways of analyzing often difficult museum specimens. The role of Raman microscopy (and also IR microscopy) in the characterization of micro-sized specimens will be illustrated in this article. Generally, it is now possible to achieve good-quality Raman microscopy spectra from sample areas as small as 1–2 µm using visible excitation (~0.5 mm has been claimed in some instances) and approximately 5–15 µm using IR and Raman FT techniques. The latest advances in confocal microscopy using visible excitation and CCD detection now means that it is possible to depth-profile suitable specimens with a resolution of approximately 1 µm or better; this is important for the analysis of coatings applied by artists to paintings.

Applications of IR and Raman Spectroscopies

Plastics

Since the first commercial plastic, Parkesine, in 1862, a huge range of functional articles have been produced in these media; many advantages were appreciated, including the ability to incorporate pigments and to mold large objects. Museums now have exhibitions devoted to plastic articles, but in recent years the problems in their conservation and storage and the control of degradation in damaged plastic exhibits have become acute. In particular, the acid ester plastics such as cellulose nitrate and cellulose acetate are prone to degradation, which has often resulted in major destruction of the articles concerned. Examples include early motion picture films, Victorian substitute 'tortoiseshell' articles, Bakelite, and children's toys, such as dolls. FT-IR and Raman spectroscopies have been instrumental in discovering the methods of degradation and the source of possible 'triggers'; suggestions have thus been made for the proper storage and conservation of plastic articles for future generations, such as dolls from the 1940s, space suits from the 1960s, and 'art nouveau' objects from the 1920s.

Glass

Degradation processes in medieval stained glass windows have been studied using FT-IR spectroscopy and the pigments applied to early specimens have been characterized using the FT-Raman technique. Similar methods have been used to study early enamels and cloisonné specimens.

Faience

Faience was produced in Egypt over 5000 years ago and may truly be considered as the first 'high-technology ceramic'. The faience body, formed from sand with additives such as lime and natron (a hydrated sodium carbonate found naturally as a mineral in dried lake beds), was shaped and modeled, and a glaze was applied and fired.

Sixteen pieces of Egyptian faience from Tell-el-Amarna have been analyzed using Raman microscopy and the red and yellow pigments identified as red ochre and lead antimonate yellow, respectively. A major problem in the characterization of the blue, white, and green pigments resulted from a swamping of the pigment Raman signals by the silica in the intact glazes. Results for the red and yellow specimens were obtained from fractured samples.

Biomaterials

The preservation and restoration of objects made from biomaterials is particularly challenging as their degradation products are complex and diverse. Examples of problems facing museum conservators include art objects made from ivory, horn, natural resins, and textiles; these objects have often become fragile and restoration is of the utmost significance and importance. Often, earlier restorative procedures, which may have been incompletely documented, are no longer satisfactory and the results of chemical deterioration of applied restoratives under the influence of solar radiation and humidity changes in storage are sadly too often plain to see.

There are several good examples in the recent literature of the successful application of vibrational IR and Raman spectroscopy to the characterization of art objects composed of biomaterials. Ivory, a generic name for the exoskeletal dental growths of certain mammalian species, has been appreciated as an art medium for thousands of years; it is soft enough to be carved and polished, yet hard enough to resist superficial weathering damage. However, the identification and attribution of archaeological ivories to species of elephant, sperm whale, narwhal, hog, and hippopotamus, for example, is often fraught with difficulty, particularly where the ivory object is small and may only be a part of a larger specimen. The observation of Schreger lines and surface morphology is extremely difficult in such cases. Very recently, Raman spectroscopy has been used to provide a suggested protocol for ivory identification and characterization and has been used successfully to determine the animal origin (sperm whale) of a Roman die excavated at Frocester Roman villa (third century AD) in the UK (**Figure 1**).

There have also been several examples of the use of Raman spectroscopy to identify genuine and fake ivory articles. **Figures 2** and **3** show some bangles, an Egyptian

Figure 1 Roman die, c. AD 300, from archaeological excavations at Frocester Villa, Gloucester, UK. Raman spectroscopy has suggested the origin of the die as sperm whale ivory.

Figure 2 Selection of ornamental jewelry consisting of three bangles assumed to be ivory but which were shown spectroscopically to be composed of modern resins, and a genuine ivory necklace.

necklace, and a carved cat, all of which were assumed to be genuine ivory dating from the seventeenth century or later; in some cases, the articles were found to be modern imitations. The case of the carved cat is very significant, as the Raman spectra show the presence of calcite that has been added to a polymer composite of poly(methyl methacrylate) and polystyrene to simulate the density of true elephant ivory. This specimen could not therefore be 300 years old as these polymers have only been known in the past 50 years! The FT-Raman spectra of true ivories from different mammal sources are shown in **Figure 4** and of the fake specimens in **Figure 5**; the spectroscopic differences are clearly discernible and provide a means of identification between fake and real specimens.

'Scrimshaw' is a special name for carved whalebone and teeth of the sperm whale; many objects in museum collections date from the eighteenth-century production of carved decorative artwork in this material by whaling sailors for their families ashore. Genuine scrimshaw is now extremely valuable and items have been created to

Figure 3 'Ivory' cat, which was identified spectroscopically as a modern imitation composed of poly(methyl methacrylate) and polystyrene resins with added calcite to give the texture and density of ivory. Reproduced with permission from Edwards HGM and Farwell DW (1995) Ivory and simulated ivory artifacts: Fourier-transform Raman diagnostic study. *Spectrochimica Acta Part A* 51: 2073–2081, © 1995 Elsevier Science B.V.

deceive the unwary. Spectroscopy has played a role in the characterization of genuine scrimshaw. **Figure 6** shows a stack-plot of Raman spectra of carved solid and hollow sperm whaletooth scrimshaw specimens, a staybusk, and a spill vase/quill pen holder; from these spectra the whale teeth and staybusk are confirmed to be genuine, but the spill vase/quill pen holder is identified as a modern fake made from polymer resin.

Similarly, IR and Raman spectroscopic studies of ancient textiles are being undertaken to derive information about the possible processes of their degradation under various burial environments, for example, Egyptian mummy wrappings, silk battle banners, Roman woollen clothing, and artistic linens from funerary depositions. A classic, topical, and ongoing controversy covers the spectroscopic studies associated with the Shroud of Turin and the nature of the pigmented areas on the ancient linen.

Ancient technologies and cultures often used naturally occurring biomaterials as decorative pigments and as functional repairing agents on pottery and glass. Recent studies have centered on the provision of a Raman spectroscopic database for native waxes and resins, which has been used for the nondestructive evaluation of archaeological items, for example, 'Dragon's blood', and it is possible to identify different sources of this material from the spectra. FT-IR spectroscopy, too, has been successful in the characterization of conifer resins used in ancient amphorae and has been particularly useful for attribution of the Baltic geographical origins of amber jewelry through its succinic acid content and for the detection of modern fakes made from phenol-formaldehyde resins that are often passed off as examples of ancient ethnic jewelry.

The identification of dammar and mastic resins that have been used as spirit-soluble varnishes on paintings

Figure 4 FT-Raman spectra of true ivory; 1064 nm excitation, 500 spectral scans accumulated, 4 cm^{-1} spectral resolution: (a) sperm whale ivory, (b) elephant ivory, and (c) walrus ivory.

Figure 5 FT-Raman spectra of fake ivory specimens; conditions as for **Figure 4**: (a) carved Victorian bangle, (b) large bangle, (c) small bangle, and (d) cat. The absence of the characteristic proteinaceous features in true ivory near 1650 and 1450 cm^{-1} and the strong phosphate mode near 960 cm^{-1} should be noted. Also, the presence of the aromatic ring bands at 3060 , 1600 , and 1000 cm^{-1} in (b) and (d) indicate a polystyrene resin content, while the carbonyl stretching band at 1725 cm^{-1} in all fake specimens indicates the presence of poly(methyl methacrylate). In the cat specimen, the band at 1086 cm^{-1} uniquely identifies a calcite additive in the specimens of imitation ivory studied. Reproduced with permission from Edwards HGM and Farwell DW (1995) Ivory and simulated ivory artifacts: Fourier-transform Raman diagnostic study. *Spectrochimica Acta Part A* 51: 2073–2081, © 1995 Elsevier Science B.V.

and on early photographic prints, and the conservation of the latter, in particular, is very important because of the embrittlement of the substrate due to exposure to light and humidity changes. Raman spectroscopy has been used to identify wax coatings on early photographs from the American Civil War (*c.*1865)

that are showing evidence of deterioration in museum collections.

Paintings

The use of IR and Raman spectroscopies for the characterization of paint pigments depends on two critical

Figure 6 FT-Raman stack-plot spectra of scrimshaw specimens: (a) hollow sperm whale tooth, (b) solid sperm whale tooth, (c) whalebone staybusk, and (d) spill vase/quill pen holder. Minor spectroscopic differences confirm the whalebone origin of the staybusk. The modern resin composition of the spill vase/quill pen holder is also unambiguously identified from the aromatic ring stretching bands at 3060 and 1600 cm^{-1} . Reproduced with permission from Edwards HGM, Farwell DW, Sedder T, and Tait JKF (1995) Scrimshaw: Real or fake? An FT-Raman diagnostic study. *Journal of Raman Spectroscopy* 26: 623–628, © 1995 Wiley.

factors: first, the ability to record good-quality spectra nondestructively from small paint flakes or chips, and second, the provision of a database of mineral, natural, and synthetic pigments on which the basis of a comparison and attribution can be made. Some examples of the success of vibrational spectroscopic methods will now be given to illustrate the potential of these techniques for pigment analysis and the conservation of degraded media.

Several databases now exist for the comparison of unknown pigments with contemporary specimens. A most useful basis for the attribution of specimens is provided by synthetic pigments, for which the dates of first manufacture or use are well established. For example, titanium(IV) oxide (TiO_2) is the most important white pigment in use today; its two major naturally occurring forms are rutile and anatase, which have been in use as paint media since 1923 and 1947, respectively. Their identification by vibrational spectroscopy is unambiguous; hence, if either is found on a disputed Renaissance painting, it could indicate a forgery or at least a recently restored work. It is interesting that the distinction between these two forms of TiO_2 is not achievable with X-ray fluorescence techniques normally used for pigment analysis in art.

A rather different example is provided by the work of Guys, who painted social life in France between 1843 and 1860. Seventy samples taken from 43 of Guys' works revealed a heavy dependence on newly synthesized and experimental pigments at that time, including Prussian

blue, Cobalt blue, and French ultramarine, sometimes in admixture and unique to an artist of his time. Restoration, therefore, needs careful attention to unusual combinations of experimental pigments. A similar study emerges from the FT-IR study of Morisot's work, *Bois de Boulogne*, this also showed the presence of novel combinations of pigments, but ones that were more stable than others that were in use at that time. Analysis of paint flakes from the *Virgin and Child*, a suspected fifteenth-century work, not only revealed the presence of expected organic binders and varnishes but also suggested that a very heavy reworking had taken place more recently, and that the work could be a forgery. On the 'Jónsbók' Icelandic manuscript, six pigments were identified by Raman microscopy, only bone white being indigenous to Iceland; the others, vermilion, orpiment, realgar, red ochre, and azurite would all have been imported.

The most important naturally occurring and synthetic inorganic pigments used over periods of time and which feature in paintings from medieval to contemporary ages are given in **Tables 1–7** along with the year of manufacture or documented use; the tables are constructed according to color or type, viz., blue, black, brown/orange, green, red, white, and yellow. These tables form the basis of dating of paintings and manuscripts by vibrational spectroscopy. The stability of inorganic mineral pigments relative to 'fugative' organic dyes was realized in mediaeval times.

Table 1 Blue inorganic pigments

<i>Pigment</i>	<i>Chemical name</i>	<i>Formula</i>	<i>Date/Source^a</i>
Azurite	Basic copper(II) carbonate	$2\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$	Mineral
Cerulean blue	Cobalt(II) stannate	$\text{CoO} \cdot n\text{SnO}_2$	1821
Cobalt blue	Cobalt(II)-doped alumina glass	$\text{CoO} \cdot \text{Al}_2\text{O}_3$	1775
Egyptian blue	Calcium copper(II) silicate	$\text{CaCuSi}_4\text{O}_{10}$	Third millennium BC/Mineral
Lazurite (from lapis lazuli)	Sulfur radical anions in a sodium aluminosilicate matrix	$\text{Na}_8[\text{Al}_6\text{Si}_6\text{O}_{24}]\text{S}_7$	Mineral/1828
Manganese blue	Barium manganate(VII) sulfate	$\text{Ba}(\text{MnO}_4)_2 + \text{BaSO}_4$	1907
Phthalocyanine blue (Winsor blue)	Copper(II) phthalocyanine	$\text{Cu}(\text{C}_{32}\text{H}_{16}\text{N}_6)$	1936
Posnjakite	Basic copper(II) sulfate	$\text{CuSO}_4 \cdot 3\text{Cu}(\text{OH})_2 \cdot \text{H}_2\text{O}$	Mineral
Prussian blue	Iron(III) hexacyanoferrate(II)	$\text{Fe}_4[\text{Fe}(\text{CN})_6]_3 \cdot 14\text{--}16\text{H}_2\text{O}$	1704
Smalt	Cobalt(II) silicate	$\text{CoO} \cdot n\text{SiO}_2 (+ \text{K}_2\text{O} + \text{Al}_2\text{O}_3)$	c.1500
Verdigris	Basic copper(II)	$\text{Cu}(\text{O}_2\text{CCH}_3)_2 \cdot 2\text{Cu}(\text{OH})_2$	Mineral

Viridian	Hydrated chromium(III) oxide	$\text{Cr}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$	1838 (?1850)

The principal dyes used by medieval dyers were indigo from woad for blue, alizarin and purpurin from madder for red, and luteolin from weld or crocetin from saffron for yellow; some had been used long before the

Middle Ages and weld was known in the Stone Age. Organic pigments have also been used on manuscripts, notably saffron, weld, indigo, woad, Tyrian purple, madder, and carmine.

Table 5 Red inorganic pigments

Pigment	Chemical name	Formula	Date/Source
Cadmium red	Cadmium selenide	CdSe	c.1910
Chrome red	Basic lead(II) chromate	PbCrO ₄ · Pb(OH) ₂	Early nineteenth century
Litharge	Lead(II) oxide	PbO	Antiquity
Realgar	Arsenic(II) sulfide	As ₂ S ₂	Mineral
Red lead (minimum)	Lead(II, IV) oxide	Pb ₃ O ₄	Antiquity
Red ochre	Iron(III) oxide + clay + silica	Fe ₂ O ₃ · H ₂ O + clay + silica	Mineral

Pigment	Chemical name	Formula	Date/Source
Barium yellow	Barium chromate	BaCrO ₄	Early nineteenth century
Cadmium yellow	Cadmium sulfide	CdS	Mineral (greenockite) + synthetic c.1845
Chrome yellow	Lead(II) chromate	PbCrO ₄ or PbCrO ₄ · 2PbSO ₄	1809
Cobalt yellow (aureolin)	Potassium cobaltinitrite	K ₃ [Co(NO ₂) ₆]	1861
Lead antimonate yellow	Lead(II) antimonate	Pb ₂ Sb ₂ O ₇ or Pb ₃ (SbO ₄) ₂	Antiquity
Lead tin yellow	Lead(II) stannate	[I] Pb ₂ SnO ₄	Antiquity?
		[II] PbSn _{0.76} Si _{0.24} O ₃	Antiquity?
Massicot	Lead(II) oxide	PbO	Antiquity
Ochre	Goethite + clay + silica	Fe ₂ O ₃ · H ₂ O + clay + silica	Mineral (and synthetic)
Orpiment	Arsenic(III) sulfide	As ₂ S ₃	Mineral
Strontium yellow	Strontium chromate	SrCrO ₄	Early nineteenth century
Zinc yellow	Zinc chromate	ZnCrO ₄	Early nineteenth century

Many natural products were extracted from lichens in the past and used to dye textiles. Notable among these were orchil for purple and crottle for brown. Other dye plants can yield greens, browns, and blacks (in the last case, e.g. marble gall from oak *Quercus* trees with added iron sulfate).

Organic pigments are prone to both fluorescence and photochemical degradation. Moreover, they often scatter only very weakly, perhaps owing to the fact that they may have been made into colorfast lakes with a mordant such as alum; hence they are difficult to identify uniquely on a manuscript owing to the lack of concentration of pigment at the sampling point. The better known organic dyes and pigments are listed in **Table 8**.

The Raman and IR spectra of organic pigments and dyes of relevance to artwork have now been recorded, including those of modern dyes such as methyl blue (a synthetic triarylmethane dye), methyl violet, and perylene reds.

Perhaps the greatest advances in recent years in the field of nondestructive pigment identification in artworks have come from historiated manuscripts that have been studied using Raman microscopy. *In situ* analyses of the brightly colored initials and borders of the fourteenth-century Icelandic 'Jónsbók', Chinese manuscripts, illuminated Latin texts and early medieval Bibles have demonstrated the power of the technique. From samples that often represented only a 20 µm fragment that had

Table 8 Organic pigments and dyes

Colour	Pigment	Formula/Composition	Origin (Date)
Blue	Indigo	Indigotin $C_{16}H_{10}N_2O_2$	Plant leaf (BC), synthetic (1878)

Brown	Sepia	Melanin	Ink of cuttlefish (c.1880)
	Van Dyck brown	Humic acids Allomelanins	Lignite containing manganese (sixteenth century?)
Green	Sap green	Organic dye	Buckthorn berry (fourteenth century?), coal-tar dye
Purple	Tyrian purple	6,6'-Dibromoindigotin, $C_{16}H_8Br_2N_2O_2$	Marine mollusc (1400 BC), synthetic (1903)
Red	Carmine	Carminic acid, $C_{22}H_{20}O_{13}$	Scale insect, cochineal (Aztec)
		Kermesic acid, $C_{16}H_{10}O_8$	Scale insect, kermes (antiquity)
	Madder	Alizarin, $C_{14}H_8O_4$	Madder root (3000 BC)
		Purpurin, $C_{14}H_8O_5$	Synthetic alizarin (1868)
Yellow	Permanent red	Various azo dyes	Synthetic (after 1856)
	Gamboge	α - and β -Gambogic acids $C_{38}H_{44}O_8$ and $C_{29}H_{36}O_6$	Gum-resin (before 1640)
	Hansa yellow	Various azo dyes	Synthetic (1900)
	Indian yellow	Magnesium salt of euxanthic acid $MgC_{19}H_{16}O_{11} \cdot 5H_2O$	Cow urine (fifteenth century)
		Quercitrin $C_{21}H_{20}O_{11}$	Inner bark of <i>Quercus</i> oak
	Saffron	Crocin $C_{20}H_{24}O_4$	Crocus flower stigma (antiquity)
	Weld	Luteolin $C_{15}H_{10}O_6$	Plant foliage (Stone Age)

fallen into the bindings of early manuscripts, FT-IR and Raman microscopies have made considerable advances in the knowledge of color hue technology in medieval times; for example, the different blues in a historiated initial could be attributed to a finer particle size and not to a dilution with other materials or colors. Useful information has also been provided about additives and binding media.

On some paintings and manuscripts, an inappropriate blend of adjacent colors or mixtures of pigments and binders was achieved; Raman microscopy has identified two examples of these in cadmium sulfide and copper arsenoacetate (which yields black copper sulfide) and egg tempera with lead white (which yields black lead sulfide). The term 'inappropriate' here refers to the instability of pigments and pigment mixtures resulting in a chemical reaction over periods of time and through aerial or substratal influences.

Where the pigment is colored, the choice of exciting line for Raman spectroscopy is extremely important because absorption of the scattered light by the sample may affect the spectrum. In such cases, the exciting line is chosen to fall outside the contour of the electronic absorption bands of the pigment. Vermilion (HgS) and red ochre (Fe_2O_3) give poor-quality Raman spectra using green excitation but give strong Raman spectra when excited with red radiation. An interesting example of the effects due to absorption of laser radiation is provided by the Raman spectra of red lead (Pb_3O_4) obtained using 514.5 and 632.8 nm excitation (Figure 7). In each case, well-defined Raman spectra are obtained, but only with 632.8 nm excitation is the spectrum that of the genuine material; that obtained with 514.5 nm excitation matches that of massicot (PbO). These observations may be

explained because red lead can be converted into massicot by heat. Red lead absorbs 514.5 nm radiation strongly, leading to localized heating that results in conversion of the irradiated particle or particles into massicot. Since 632.8 nm radiation is not absorbed by the red lead, there is minimal local heating with this exciting line and thus no decomposition.

For colored pigments, the absorption of exciting radiation can be used to advantage to produce enhanced Raman scattering through the resonance Raman effect. This is particularly useful for weakly scattering species, and selection of excitation within the contour of an electronic absorption band of a chromophore can produce a spectral intensity several orders of magnitude larger than that obtained in conventional Raman spectra. A classic example of this is provided by the deep blue mineral lapis lazuli, $Na_8[Al_6Si_6O_{24}]S_m$ where the species S_2^- and S_3^- are responsible for the color. The species S_3^- , although present to an extent of <1% in the pigment, gives such an intense Raman spectrum with green-red excitation that no bands due to the host lattice are observed. Other techniques fail to discriminate the presence of S_3^- in the aluminosilicate lattice.

The Raman spectrum is sensitive to both composition and crystal form, as is demonstrated by titanium(IV) dioxide, the most important white pigment in use today. White pigments normally present considerable problems in pigment identification, comprising sulfates, carbonates, and phosphates, which are easily distinguished in Raman spectroscopy (Figure 8). The symmetric vibration of the anion gives rise to an intense band at $\sim 1000\text{ cm}^{-1}$ for sulfates, $\sim 1050\text{ cm}^{-1}$ for carbonates, and $\sim 960\text{ cm}^{-1}$ for phosphates. The exact wavenumber of these bands are also sensitive to the cation (1050 cm^{-1} for $PbCO_3$ and

Figure 7 Illustration of the effect of wavelength of laser excitation on the Raman spectra of a pigment, red lead (Pb_3O_4), excited with (a) 514.5 nm and (b) 632.8 nm radiation. The genuine spectrum is (b); the spectrum excited by green radiation in (a) corresponds to massicot (PbO), converted from Pb_3O_4 by localized heating in the laser beam. 1085 cm^{-1} for CaCO_3). This factor becomes extremely important in database construction since artistic vocabulary generally describes the color rather than a precise mineral origin, for example, cadmium yellow, although strictly CdS has also been designated for organic substitutes of similar hue. Old recipes for obtaining pigment colors are often vague and employ unidentifiable materials; the same chemical compound or mixture can even have different names according to geographical locality or historical period. For example, three contemporary samples designated Naples Yellow, assumed to be $\text{Pb}_2(\text{SbO}_4)_2$ – a lead antimonate – have been shown by Raman spectroscopy to be a lead antimony oxide, $\text{Pb}_2\text{Sb}_2\text{O}_6$, another oxide, $\text{Pb}_2\text{Sb}_2\text{O}_3$, and the third sample mainly $\text{Pb}_2(\text{CrO}_4)_2$, but also containing PbCO_3 . None of the samples tested actually proved to be Naples Yellow of the assumed formula!

Medieval Manuscripts

Most pigments in medieval manuscript illuminations are inorganic. They are coated with a small quantity of binding material and deposited on parchment that has previously been rubbed with pumice. The small size of the illuminations limits the number of spectroscopic samplings.

The blue color in a set of six French manuscripts from the twelfth century was studied in different kinds of initial – historiated (with a descriptive scene), decorated, or simply colored – which showed variable hues of pure blue, gray, and sometimes violaceous. Raman microspectra obtained from all of the samples show common features: they are dominated by a strong band at 548 cm^{-1} , with weaker bands at 260, 585, and 1098 cm^{-1} . This group of four bands is characteristic of ultramarine blue and reveals the presence of only this pigment. In the blue–gray samples, microscopic observation showed tiny black particles that were identified by their Raman spectra as graphite.

Ultramarine has been identified in a manuscript commentary on *Ezekiel*, c. AD 1000, in the abbey of St Germain, Auxerre, France. The pigment ultramarine is first mentioned in written sources in the thirteenth century. This discovery established for the first time that the pigment was in fact introduced into Europe almost two centuries earlier. The manuscript was to reveal more fascinating details. Part of the dedication image at the beginning of the manuscript is a figure representing the Abbot, Hildric, kneeling before St Germain, who died around 448 and is buried in the abbey. From the spectrum of the pigments, it was established that the Abbot's blue garments were painted with indigo (woad) while

only the patron saint's more glorious garment was covered with the rare and expensive lapis lazuli, thus emphasizing his importance.

The letter 'I' in the Lucka Bible at the beginning of the Book of Genesis displays seven scenes representing the seven days of Creation. The varied palette (Table 9)

Figure 8 Raman spectra of white pigments; differentiation between (a) lead white (PbCO_3), (b) chalk (CaCO_3), and (c) bone white ($\text{Ca}_3(\text{PO}_4)_2$). has been well characterized using Raman microscopy (Figure 9).

The Skard copy of the Jónsbók Icelandic Law Code dates from c.1360 and is one of the most outstanding examples of an Icelandic medieval manuscript. The pigments have been analyzed by Raman microscopy; three historiated initials and approximately 15 illuminated initials with associated background paintings and embellishments have been examined. Six pigments were identified unambiguously by Raman microscopy: vermilion, orpiment, realgar, red ochre, azurite, and bone white. Neither red lead nor lead white, pigments commonly used in Northern Europe, was identified on the manuscript: this raises questions as to the availability of these pigments in Iceland, to which they are not native, and of the effectiveness of the trading routes. Examples of two historiated initials and the Raman spectra of the pigments used are shown in Figure 10.

An elaborately historiated initial 'R' on a sixteenth-century German choir book has been studied by Raman microscopy and no fewer than eight pigments have been identified, namely, azurite, lead tin yellow, malachite, vermilion, white lead, red lead, carbon, and massicot (Figure 11).

Raman microscopy demonstrated that in this case the two shades of blue on the garments of the right-hand figure, although appearing to be due to different pigments, arise from the same pigment, azurite, the illuminator having used less azurite and proportionately more binder to produce the lighter shade without choosing to add any white pigment, such as lead white, to gain the same effect. The azurite used in the deeper blue robe arises from coarse grains of pigment ($\sim 30\text{ }\mu\text{m}$ diameter) whereas the lighter blue used in the undergarment arises from fine grains ($\sim 3\text{ }\mu\text{m}$ diameter). The effect of the particle size on the depth of color of a powder is a common feature of powdered materials, whose color is determined by diffuse reflectance. As the particle size is reduced, the average depth to which radiation penetrates before being scattered is also reduced and hence the depth of color is reduced.

The angel's wing and podium are painted in malachite, which is a basic copper carbonate similar to

Table 9 The Raman bands of inorganic pigments in the Lucka Bible

Pigment	Raman bands (cm^{-1})
Azurite	248w, 404vw, 770m, 838vw, 1098m, 1424w, 1578w

azurite. Both azurite and malachite have a similar provenance in that they are both associated with secondary copper ore deposits, but their spectra are very different.

It is of particular interest that the dark gray color of the pillar top is not obtained via a single pigment but by

color subtraction of a mixture of at least seven pigments: white lead, carbon, azurite, as well as small amounts of vermilion, red lead, massicot, and lead tin yellow type I. The mixture is evident at $\times 100$ magnification by Raman microscopy, whereby each individual pigment grain may be identified (**Figure 12**).

Figure 10 The historiated initials (a) 'P' and (b) 'S' from the Icelandic Jónsbók with the Raman spectra of pigments contained therein. The combination of vermillion and red ochre in the 'P' should be noted. The spectrum of bone white has been obtained from the letter 'H' (not shown). Wall Paintings

The application of FT-Raman spectroscopy to the study of red pigments from English early medieval wall

paintings in the Chapter House of Sherborne Abbey and the Holy Sepulchre Chapel in Winchester Cathedral (Figure 13) has been reported. The complexity of the spectra can be observed in Figure 14, where the pigment

Figure 11 Elaborately historiated initial 'R' in a sixteenth-century German choir book, with Raman microscopy spectra of selected pigmented regions. Reproduced with permission from Clark RJH (1995) Raman microscopy: Application to the identification of pigments on medieval manuscripts. *Chemical Society Reviews* 24: 187–196, © 1995 The Royal Society of Chemistry.

and substratal features are clearly differentiated. The operations of the two monastic houses were very different, as the Sherborne Abbey pigment consisted of pure vermilion, whereas that of Winchester Abbey was a 3:1 mixture of red ochre and vermilion. In both cases, spectral features due to sandstone and marble could be seen, but no identifying feature could be ascribed to a plaster substrate.

The biodeterioration of the Renaissance frescoes in the Palazzo Farnese, Caprarola, Italy, arising from aggressive colonization by the lichen *Dirina massiliensis* forma *sorediata* has been studied using Raman microscopy. Over 80% of the masterpieces painted by Zuccari in 1560 have now been destroyed. The role of the lichen metabolic products and the ability of primitive organisms to survive hostile environments generated by large concentrations of heavy metals such as mercury, lead, and antimony are now being understood as a result of these studies, which will assist conservators in future projects.

The red pigment on the Carolingian frescoes in the crypt of the Abbey of St Germain at Auxerre shows up to 13 layers of paint identified by Raman microscopy, and vermilion and iron(II) oxide have both been found.

The North American paleo-Indian shelters at Seminole Canyon, at the confluence of the Rio Grande and Devils Rivers, have provided the Raman spectra of the oldest cave paintings yet studied. From a limited palette, these 3500-year-old pictographs have yielded red, white, and black colors identified as red ochre, calcium oxalate monohydrate (whewellite), and manganese(IV) oxide, respectively. In addition, the black pigment showed traces of an organic additive recently identified from DNA profiling as bison or deer bone marrow, presumably added in a symbolic ritual.

FT-IR spectroscopy, too, has had considerable success in the identification of pigments and associated materials in paintings and manuscripts. In particular, the use of IR microspectroscopy has proved to be an essential

Figure 12 Portion of top of column of historiated initial 'R' shown in Figure 11; the individual pigment grains can be clearly seen under the $\times 100$ magnification and can be separately identified using Raman microscopy. Reproduced with permission from Clark RJH (1995) Raman microscopy: Application to the identification of pigments on medieval manuscripts. *Chemical Society Reviews* 24: 187–196, © 1995 The Royal Society of Chemistry.

Figure 13 Holy Sepulchre Chapel, Winchester Cathedral. Wall painting of c.1175–85 on the east wall depicting the *Deposition, Entombment, Maries at the Sepulchre and the Harrowing of Hell*. prerequisite for the scientific examination of complex pigment mixtures. Generally, however, inorganic mineral pigments are not well characterized in the IR because of their low-band wavenumbers; hydroxyl groups in

hydrated minerals cause problems in absorption and the substrates themselves, for example, cellulose, linen, or starch, often give rise to broad backgrounds. IR spectroscopy, therefore, is much more applicable to organic pigments, binders, and mixtures.

One project dealing with medieval manuscripts has had as its objective the application of small-particle-analysis techniques to the study of pigments in medieval Armenian and Byzantine manuscripts. At the University of Chicago, 10 decorated manuscripts were sampled (Table 10). These manuscripts represent a broad chronological span ranging from the tenth century to the post-Byzantine era (sixteenth century or later).

Interpretation of IR spectra was complicated by the fact that the pigment samples often contained several components in addition to the pigment. These additives often served as binding media – thickening agents or extenders, for example. Because the amount of pigment is small relative to the amounts of these nonpigment components, the spectral bands of the pigment are often difficult to distinguish from interfering spectral bands of nonpigment components. Chromatographic separation before spectroscopic analysis was not feasible because of the insolubility and limited quantity of the samples. Spectral subtraction has been used in many cases as a means to 'separate' the components.

The IR spectrum of a yellow pigment sample from manuscript (MS) 46 (Haskell gospels) shows several bands that can be attributed to egg yolk, a typical medium used in mediaeval times, as well as calcium carbonate and kaolin. The absorption bands at 3382, 3298, and 1600 cm^{-1} suggested that a primary amine is present. Putrescine (1,4-diamino-butane), an amine found in decaying proteinaceous matter, has similar spectral features. Because parchment (being of animal skin origin) would be subject to putrefaction if not properly preserved, this amine could be a product of bacteriological degradation.

Although the pigment was not identified in this case, the information that egg tempera is present as the binding medium is valuable; the binding medium in MS 965 is hide glue.

Pigment components have also been identified from their IR spectra. The IR spectrum obtained from a purple pigment removed from MS 965 showed bands due to ultramarine blue and white lead. A red pigment (possibly cochineal) must also be present with the blue to produce the purple color.

In MS 972 (Archaic Mark), the presence of Prussian blue from the IR spectrum indicates possible restoration because Prussian blue, a synthetic dye, was not available until 500 years later.

Another example of the use of FT-IR spectroscopy in the authentication of paintings is provided by the analysis of the *Virgin and Child*, a fifteenth-century Italian painting

Figure 14 FT-Raman spectra of twelfth-century wall paintings in (A) Sherborne Abbey ((a) red pigment, (b) vermilion, (c) unpainted stone, (d) calcite) and (B) Winchester Cathedral ((a) red pigment, (b) vermilion, (c) red ochre). Table 10 University of Chicago Special Collections manuscripts analyzed by FT-IR spectroscopy

Manuscript number	Name
972	Archaic Mark
1054	Elfreda Bond Goodspeed <i>Gospels</i>
965	Rockefeller–McCormick <i>New Testament</i>
131	Chrysanthus gospels
232	Greek gospels
46	Haskell gospels
129	Nicolaus gospels
727	Georgius gospels
879	Lectionary of Constantine the reader
948	Lectionary of St Menas the wonder worker

on panel. There were already stylistic doubts and, although IR spectroscopy confirmed the presence of egg tempera as a binding medium, the blue pigment was not azurite or lapis lazuli. A prominent IR absorption at 2091 cm^{-1} identified the blue pigment on the Virgin's robe as Prussian blue, unknown before 1704. Hence, the

painting has either been very heavily reworked or is possibly a nineteenth-century copy of an earlier work.

This article is reproduced from the previous edition, volume 1, pp 18–24, © 1999, Elsevier Ltd.

Introduction

Ion sources for atmospheric-pressure ionization (API) in mass spectrometry (MS) were first described in 1958 by Knewstubb and Sugden. The work of the research group of Horning and Carroll in the late 1960s and early 1970s resulted in a system commercially available from Franklin GNO Corp. These types of instruments were used mainly in the study of ion–molecule reactions in gases in the atmosphere. Furthermore, in 1974 this type of instrument was applied with an atmospheric-pressure corona discharge ion source in the coupling of liquid chromatography to MS (LC-MS). Despite the promising results, the technique did not attract much attention at that time.

Subsequently, several other API instruments were described and built. The most successful commercial instrument was the Sciex TAGA (trace atmospheric gas analyser), whereas API systems were also available from Extranuclear and Hitachi. In the late 1980s, the TAGA API-MS system was reengineered by Sciex for online LC-MS and was called the API-III. This system was applied by a growing group of scientists, especially within pharmaceutical companies. In the early 1980s, Yamashita and Fenn fundamentally investigated the potential of electrospray ionization in an API source. This research led to another approach to LC-MS using an API system. In 1988, Fenn and coworkers demonstrated that with this electrospray system it was possible to perform the MS analysis of high-molecular-mass proteins via multiple charging. As a result of this observation, API-MS went through a period of tremendous growth, the end of which is certainly not yet here. In the mid-1980s, similar API technology was also applied in the coupling of inductively coupled plasmas (ICP) to MS.

At present, there are three major application areas of API-MS:

- air or gas analysis,
- online LC-MS, and
- ICP-MS.

In this article, technical and instrumental aspects of API-MS are discussed and a number of typical applications are briefly reviewed.

API Ion Source Design

An API ion source generally consists of four parts:

1. the sample introduction device, the design of which is highly dependent on the type of application;
2. the actual ion source region, that is the region where the ions are generated;
3. an ion sampling aperture, where the ions are sampled from atmospheric pressure into the vacuum system of the MS; and
4. an ion transfer system, where the pressure difference between the atmospheric-pressure source and the high-vacuum mass analyser is bridged and the ions entering through the ion sampling aperture are preferentially transferred and focused into the mass analyser region.

The proper design of parts 3 and 4 is of utmost importance, as it determines to what extent the very high ionization efficiency that can be achieved in an API source actually becomes available to the analytical applications. The inevitable ion losses in the sampling and transfer regions should be kept to a minimum.

Ion Sampling Aperture and Ion Transfer System

An API source system consists of a region where the ions are generated. This region can have a relatively large volume of several litres, although in practice only the ions that come close to the ion sampling aperture are efficiently sampled into the MS. Therefore, in many systems the ions are generated just in front of the ion sampling aperture. A general scheme of an API source is shown in **Figure 1**.

In the early API systems, the ion sampling aperture consisted of a 25–200 μm i.d. pinhole in a metal plate. The size of the pinhole is limited by the pumping capacity of the vacuum system of the MS. In the first prototypes, the pinhole inner diameter was only 25 μm , while in the Sciex TAGA a larger pinhole could be applied, because of the high pumping efficiency of the cryogenic vacuum-pumping system available in this instrument.

The sampling of ions through an orifice in a plate or in the tip of a cone is used in many commercial API

Figure 1 Schematic diagram of a typical API source, as for instance used in LC-MS.

systems. However, two alternative ion sampling devices based on the transport of ions through capillary tubes have been developed and commercialized. The first, designed by Fenn and coworkers and subsequently commercialized by Analytica of Branford, incorporates a 100–150 mm $\times$ 0.5 mm i.d. glass capillary. Both ends of the glass capillary are coated with metal, for example, silver, gold or platinum, in order to define the potential at both tips. The use of an insulating glass capillary enables independent control over the potentials applied in the atmospheric-pressure ion source region and in the ion acceleration region inside the vacuum. The second alternative to the ion sampling orifice is a heated stainless steel capillary, initially proposed by the group of Chait and subsequently commercialized by Finnigan.

In the strong cooling that takes place upon the expansion of a gas into a vacuum chamber, as takes place in an electrospray source, the ions act as condensation nuclei for water and solvent molecules. As a result, clusters of analyte ions and numerous solvent molecules are formed. This cluster formation can be counteracted or avoided in two ways: either by preventing the solvent ions from reaching the ion sampling orifice or by increasing the temperature of the gas, vapour, and ion mixture entering the vacuum. By flushing the area just in front of the sampling orifice with a stream of dry nitrogen, the solvent vapour can be swept away, whereas the ions are forced to pass through this nitrogen 'curtain' by the application of an electric field between the curtain plate and the orifice plate in **Figure 1**. An additional benefit of a curtain gas is the prevention of other neutral contaminants, such as particulate material, from entering the ion sampling orifice or capillary. This is important for the ruggedness required for day-to-day use of LC-MS, for example, in the analysis of large series of biological samples. A curtain or

counter-current gas is applied in the sources built by Sciex, Analytica of Branford, and Hewlett-Packard. Alternatively, the temperature of (part of) the ion source or of the ion sampling capillary can be increased to avoid the formation of clusters between analyte ions and solvent molecules. This obviates the need for a curtain gas, but also leaves the ion sampling device unprotected from contamination by particulate material.

Ions are sampled from the atmospheric-pressure region and together with nitrogen, which is applied as nebulizing gas as well as curtain gas, enter the vacuum system. The low-pressure side of the ion sampling pin-hole or the low-pressure end of the ion sampling capillary acts as a nozzle, where the mixture of gas, solvent vapour, and ions expands. The expanding jet is subsequently sampled by means of a skimmer into a second vacuum stage. In most systems, the region between the nozzle and the skimmer, which is pumped by a high-capacity rotary pump, contains an additional lens, for example, a ring or tube electrode, to preferentially have the ions sampled by the skimmer. From a gas dynamics point of view, it might be important to position the skimmer just in front of the Mach disk of the expansion. However, because ions are preferentially sampled, the positioning of the skimmer relative to the Mach disk does not appear to be very important. In some systems, nozzle and skimmer are actually not precisely aligned in order to reduce the number of neutral molecules in the highly directed flow from the nozzle entering the region with higher vacuum. Optimum ion transfer is achieved by means of a tube lens between nozzle and skimmer.

At the lower pressure side of the skimmer, a second expansion step takes place. In older systems, the ions entering through the skimmer were extracted, transferred and focused into the mass analyser region by means of a set of conventional flat lenses. Later, it was determined that a more efficient ion transfer and focusing can be achieved by means of an RF-only quadrupole, hexapole or octapole device (cf. **Figure 1**). These types of ion transfer and focusing devices are especially in use in systems for LC-MS. In other systems, as used for ICP-MS for instance, ion focusing is achieved by means of a combination of Einzel lenses and a Bessel box (cf. **Figure 2**).

The source designs described so far are used in combination with a (triple) quadrupole instrument. Modifications of this design are required in the coupling to other types of mass analysers, for example, the implementation of a gate or ion pulse electrode for use in combination with ion-trap and time-of-flight mass analysers.

Sample Introduction Devices

A wide variety of sample introduction devices is available for gas analysis by API-MS. In the study of atmospheric

Figure 2 Schematic diagram of a typical API source for ICP-MS.

processes, direct sampling of ionic species and clusters in various atmospheric layers may be performed. For these *in situ* studies, air is directly sampled into the system, eventually through specially designed sampling tubes. Alternatively, gases may be sampled and mass analysed after ionization by electrons from a corona discharge (similar to APCI).

For use in combination with LC-MS and other liquid-introduction techniques, two main types of sample introduction devices are available: one for electrospray ionization and one for APCI.

The devices for APCI consist of a heated nebulizer, which is a combination of a concentric pneumatic nebulizer and a heated quartz tube for droplet evaporation. Additional auxiliary gas is used to flush the evaporating droplets through the vaporizer into the actual ionization region. A schematic diagram of such a device is shown in **Figure 3**. Reactant ions for APCI are generated in a point-to-plane corona discharge in the atmospheric-pressure ion source. The discharge needle is operated at 3–5 kV and provides a corona emission current of a few microamperes.

For electrospray ionization, initially, 100 μm i.d. stainless-steel capillaries, that is, hypodermic needles, were used for sample introduction. With such a device, the flow rate is limited to $\sim 10 \mu\text{L min}^{-1}$, which is too high for many biochemical applications and too low for effective LC-MS coupling. Therefore, the initial system was modified.

For biochemical applications, the dimensions of the introduction capillary were decreased to a few micrometer internal diameter capillaries, mostly a glass or fused silica. This approach is called nanoelectrospray as it allows the continuous introduction of between 5 and 100 nL min^{-1} of a liquid into the API source. Nanoelectrospray is especially useful for applications where the sample amount is limited. In this way, it is possible to perform a series of MS experiments with a minute

Figure 3 Schematic diagram of a sample introduction device for APCI: a heated nebulizer.

amount of sample, for example, 30 min of various MS experiments with only 1 μL of sample.

For LC-MS applications, the electrospray nebulization process was assisted by pneumatic nebulization; that is, a nebulization gas at a high linear velocity is forced around the electrospray needle. This approach, introduced by Sciex as ionspray in 1986, was subsequently adopted by other instrument manufacturers and is now the most widely applied approach to LC-MS via electrospray interfacing. A schematic diagram of a typical sample introduction device for LC-MS via pneumatically assisted electrospray is shown in **Figure 4**.

Significant research has taken place since then concerning the optimum geometry of the spray device in the atmospheric-pressure ion source. Although initially the spray device was positioned axially relative to the ion sampling orifice, other instrument manufacturers use a different setup, for example the spray device positioned orthogonally to the ion sampling orifice, or at an angle of 45° , eventually with a perpendicular heated gas probe to assist in droplet evaporation. The two main perspectives in this type of research are the ability to introduce a higher liquid flow rate while still avoiding the risk of clogging the ion sampling orifice and the ability to introduce samples containing significant amounts of nonvolatile material, for example samples from biological

Figure 4 Schematic diagram of a pneumatically-assisted electrospray sample introduction device.

fluids after minimum sample pretreatment, or LC mobile phases containing phosphate buffers. Although the advantages of the alternative positioning of the spray device is well documented for biological fluids, the evidence for the possibilities of the use of phosphate buffers is less convincingly demonstrated.

For use in ICP-MS, ions are sampled directly from the inductively coupled plasma. Special precautions are required related to the high temperatures in the plasma. A schematic diagram of an ICP-MS system is shown in **Figure 2**. In most cases, the liquid sample, which can be introduced directly from a vial, of a liquid-phase separation technique such as LC is nebulized into a separate spray chamber. The aerosol, containing the smaller droplets, is transported by argon to the torch, where the ICP is generated and sustained. In this so-called ICP flame, the analytes are atomized and ionized. The ions are directly sampled from the flame by the ion sampling aperture for mass analysis.

Ionization in API Conditions

Ionization in an API source can take place in a variety of ways, depending on the type of applications. The various way are briefly reviewed in the following sections.

Gas-Phase Ionization

In initial applications of API sources for gas analysis and monitoring of atmospheric ionic processes, either direct sampling of the ions present in flames or in the atmosphere was applied or ions were generated by means of electrons from an electron-emitting ^{63}Ni foil or by means of a corona discharge. Subsequently, the corona discharge became a popular method for generating ions, in both gas analysis and APCI in LC-MS applications.

In an API source equipped with a ^{63}Ni foil, energetic electrons ionize the nitrogen present in a series of

consecutive steps:

Similarly, other gases may be ionized. In the presence of traces of water in the ion source, these ionic species react with the water molecules:

The main ionic species generated, that is $\text{N}_4^{\bullet+}$ and $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$, may enter in ion-molecule reactions, leading to charge exchange of proton transfer reactions. This is valid for positive-ion acquisition, whereas negative ions may be generated either by electron-capture processes with electrons or via proton-transfer ion-molecule reactions starting from $\text{OH}^-(\text{H}_2\text{O})_n$ for instance.

The same reactant ions are formed in positive-ion mode in a point-to-plane corona discharge. Approximately 3–9 kV is applied at the corona discharge, creating a corona current of 1–5 μA , depending on the point-to-plane distance and the composition of the vapours in the ion source. Corona discharges are very complicated processes that involve avalanches of ionization reactions by ion-molecule and electron-molecule collisions together with quenching processes, as discussed in detail by Meek and Craggs.

In the positive-ion mode, the ionization of analyte molecules follows the general rules of chemical ionization; that is proton transfer may take place when the proton affinity of the analyte molecule exceeds that of the reagent gas, leading to protonated molecules:

In addition, various adduct ions and cluster ions with solvent molecules may be generated. In the negative-ion mode, either electron-capture products $\text{M}^{\bullet-}$ or deprotonated molecules $[\text{M}-\text{H}]^-$ may be generated, although the electron-capture products may further react in ion-molecule reactions to form different ionic species.

The positive-ion mass spectra obtained from APCI and conventional medium-pressure CI might show differences because the mass spectrum in medium-pressure CI is more determined by the reaction kinetics, whereas in APCI, due to the longer residence times of ions in the sources as well as the more frequent ion-molecule collisions, the mass spectrum more reflects the thermodynamic equilibrium conditions.

Figure 5 Ion envelope of multiply charged ions, obtained in the electrospray ionization of haemoglobin. In the spectrum, the m/z and charge state of the ions are indicated. The spectrum consists of two series: one due to a Hb- α chain (M_r 15 126 Da) and one due to a Hb- β^A chain (M_r 15 867 Da).

Liquid-Based Ionization

The liquid-based ionization technique in API-MS is applicable in electrospray interfacing as well as with a heated nebulizer introduction under certain conditions, that is, without switching the corona discharge electrode on, and for certain compounds. In this article, the discussion is restricted to electrospray interfacing.

In electrospray ionization and interfacing, a high potential, typically 3 kV, is applied to a liquid emerging from a capillary. This causes the liquid to break into fine threads emerging from the so-called Taylor cone formed at the capillary tip. The threads subsequently disintegrate into small droplets. The electrohydrodynamic or Rayleigh disintegration results from autorepulsion of the electrostatically charged surface which exceeds the cohesive forces of surface tension (the Rayleigh limit). In this electrospray nebulization process, uniform droplets in the 1- μ m diameter range are formed. These charged droplets shrink by solvent evaporation, whereas electrohydrodynamic droplet disintegration again takes place as soon as the Coulomb repulsion of the surface charges exceeds the surface tension forces. The offspring droplets generated in the field-induced droplet disintegration process carry only 2% of the mass of the parent droplet and 15% of its charge. Analyte ions in these offspring droplets, present as preformed ions, desorb or evaporate into the gas phase and become available for mass analysis. The ion evaporation process, described first by Iribarne and Thomson and generally considered as the most important ionization mechanism in electrospray ionization, is a process which thermodynamically corresponds to bringing a solvated ion from the surface of a charged droplet to infinity. Below a certain size/charge ratio for a droplet, the Gibbs free energy of solvation of an ionic species present in the droplet will exceed the energy required to bring this species as a solvated ion from infinity to the surface of the droplet. Under these conditions, ion evaporation is possible. According to Iribarne

and Thomson, ion evaporation will take place instead of electrohydrodynamic disintegration when the critical ion evaporation droplet radius exceeds the Rayleigh limit.

Electrospray ionization is especially effective for analytes that are present as preformed ions in solution, for example, organic acids or bases that are present as deprotonated or protonated molecules, respectively, at suitable pH values, quaternary ammonium compounds and so on. For biomacromolecules like proteins, which exist in solution as a distribution of ionic species carrying different numbers of charge, electrospray ionization results in a spectrum containing an ion envelope of multiply charged ions (see **Figure 5**). To a first approximation, this mass spectrum reflects the charge-state distribution of the protein in solution. As the ion separation in a mass analyser is based on mass-to-charge ratio, the multiple charging allows the mass analysis of large molecules within the limited m/z range of, for instance, a quadrupole mass spectrometer.

The observation of multiple charging of proteins in electrospray ionization attracted much attention: all major instrument manufacturers introduced an API system to be used in combination with an electrospray interface. At the same time, it was found that electrospray ionization is not only suitable for the mass analysis of large molecules, but is also a very efficient ionization technique of small polar or ionic molecules, for example, drugs and their metabolites. In the past few years, hundreds of dedicated API-MS systems equipped with electrospray and APCI interfaces have found their way into many different laboratories, especially within pharmaceutical companies and biochemistry/biotechnology laboratories.

Plasma-Based Ionization

A plasma is an ionized gas that is macroscopically neutral; that is, an equal number of positive and negative particles are present. In ICP-MS, the gas used to generate the plasma is argon, which has a high ionization

energy (15.76 eV). The hot argon plasma has the capability to atomize most samples, and excite and ionize most elements of the periodic table. The plasma is generated in a torch. A high-frequency generator, typically operated at 27 or 40 MHz and with a power of 1–2 kW, is used to produce a high-frequency field through an induction coil, which is positioned at the outside of the torch. In this way, the argon plasma is produced; that is, the argon is ionized and the plasma is sustained. Liquid samples are nebulized and the aerosol is injected into the plasma for atomization and ionization. The ionized atoms generated in this way are sampled by the ion sampling aperture and mass analysed.

Applications

Gas Analysis

There are a number of applications of API-MS in gas analysis, for example, the study of environmental air contamination, human breath analysis, the study of (ionic) processes in the atmosphere, the detection of trace impurities in gases that are important in microelectronic manufacturing processes, or the identification of ions in flames. The power of this technique is perhaps best illustrated by the ability to achieve detection limits in the ppt range for oxygen, water, methane and carbon dioxide in high-purity gases like hydrogen, nitrogen, argon and helium. A proper characterization of the trace impurities in these gases is of utmost importance in semiconductor processing. Using a mobile API-MS system, such as the Sciex TAGA, real-time environmental monitoring of TNT, industrial emissions, PCBs, and other environmental contaminants in the ground-level troposphere are possible.

LC-MS

The use of API-MS for the online LC-MS coupling is the largest commercial field of application of API-MS. From the early 1990s, when the potential of API-MS for LC-MS, and especially its robustness and ‘user-friendliness,’ were substantially demonstrated, an astonishingly large number of API-MS systems for LC-MS were purchased. Particularly in various stages of drug development within pharmaceutical industries, the use of API-based LC-MS is preferred over the more conventional LC-UV system. In general, better reliability, confirmation, selectivity and sensitivity are achieved in LC-MS systems. In this way, high-throughput quantitative bioanalysis is possible. In addition, API-based LC-MS systems using electrospray or atmospheric-pressure chemical ionization (APCI) interfacing and ionization are applied for the quantitative and qualitative analyses of a wide variety of polar compounds in numerous matrices in a number of other fields, for example, pesticides,

herbicides, and their metabolites and degradation products in environmental samples, natural products in plant extracts and cell cultures, peptides, proteins and other biomacromolecules in biochemical and biotechnological applications.

ICP-MS

ICP-MS is used in practically every discipline where inorganic analytical support is required. This includes environmental, geological, biological, medical, nuclear, metallurgical (semiconductor industry), and nutritional studies. An important advantage of ICP-MS in quantitative analysis, required in many fields of application, is the substantial gain in precision and accuracy that can be achieved by the use of isotope-dilution mass spectrometry, where stable isotopes or long-lived radioisotopes of the elements to be analysed are added as internal standards, for example, the use of ^{111}Cd in the analysis of ^{114}Cd . In addition, ICP-MS can be extremely useful in speciation. In this respect, there is a growing interest in the use of ICP-MS directly coupled to LC or capillary electrophoresis for speciation and analysis of elements of toxicological interest, like As, Se, Pb, and Hg.

Atomic Absorption, Methods and Instrumentation

Steve J Hill and Andy S Fisher, University of Plymouth, UK

This article is reproduced from the previous edition, volume 1, pp 24–32, © 1999, Elsevier Ltd.

Introduction

Atomic absorption spectroscopy has become one of the most frequently used tools in analytical chemistry. This is because for the determination of most metals and metalloids the technique offers sufficient sensitivity for many applications and is relatively interference free. There are two basic atom cells (a means of converting the sample, usually a liquid, into free atoms) used in atomic absorption spectroscopy: (1) the flame and (2) the electrothermal heating of a sample cell. It is generally acknowledged that if sufficient analyte is present in the sample, then it should be determined using a flame technique because this has added advantages of being rapid (assuming only a few elements need be determined) and, in comparison with alternative techniques, very simple to use. Electrothermal atomic absorption spectroscopy (ETAAS) or electrothermal vaporization atomic absorption spectroscopy (ETVAAS) requires more operator skill and is less rapid, but yields substantially superior limits of detection when compared with flame atomic absorption spectroscopy (FAAS). This section describes some of the methods and instrumentation that have been developed for both flame and electrothermal techniques of atomic absorption spectroscopy.

Instrumentation

The basic principle of both FAAS and ETAAS is that a sample is introduced into the atom cell, where it is desolvated and then atomized. The analyte atoms so formed then quantitatively absorb light in a way that is proportional to the concentration of the atoms of the analyte in the cell. The light, which is at a specific wavelength, is then isolated from other wavelengths that may be emitted by the atom cell and then detected. Thus, much of the instrumentation used for ETAAS and FAAS is identical. Both techniques require a similar light source, background correction system, line isolation device (monochromator or polychromator), detector (photomultiplier or charge-coupled device), and readout system. Each of these components is discussed in the following sections, together with details of the individual atom cells (flame and the electrothermal atomizer) and sample introduction systems.

Light Source

The fundamental requirement of the light source is to provide a narrow line profile with little background. It should also have a stable and reproducible output with sufficient intensity to ensure that a high signal-to-noise ratio is obtained. Two basic types of light source are used for atomic absorption, of which the hollow-cathode lamp (HCL) is the more commonly used. This is a lamp in which the cathode is coated with the analyte metal of interest. Within the lamp, inert filler gas (neon or argon) is ionized by an electric current and these ions are then attracted by the cathode. The inert gas ions bombard the cathode and in so doing excite the metal ions coated on it. It is this excitation of the metal that produces the emission of radiation with wavelengths characteristic of the analyte. HCLs are available for most metallic elements. A schematic diagram of a HCL is shown in Figure 1.

Electrodeless discharge lamps are used less frequently than the HCLs except for analytes such as arsenic and selenium. These lamps may be excited using either microwave energy (although these tend to be less stable) or radiofrequency energy. The radiofrequency-excited lamps are less intense than the microwave-excited ones, but are still 5–100 times more intense than a standard HCL. In the electrodeless discharge lamp, a bulb contains the element of interest (or one of its salts) in an argon

Figure 1 Schematic representation of a hollow-cathode lamp. Reproduced from Ebdon L (1998) *Introduction to Analytical Atomic Spectrometry*, with permission from Wiley.

Figure 2 Electrodeless discharge lamp. Reproduced from Ebdon L (1998) *Introduction to Analytical Atomic Spectrometry*, with permission from Wiley.

atmosphere. The radiofrequency energy ionizes the argon and this, in turn, excites the analyte element, causing it to produce its characteristic spectrum. For analytes such as arsenic and selenium, these lamps give a better signal-to-noise ratio than HCLs and have a longer useful lifetime. A schematic diagram of an electrodeless discharge lamp is shown in **Figure 2**.

Background Correction Systems

There are basically three types of automatic background correction system available for atomic absorption, although manual methods such as the use of nearby nonatomic absorbing lines to estimate background absorbance may also be used. The three main automatic methods are the deuterium or hydrogen lamp, the Zeeman effect, and Smith–Hieftje background correction. The deuterium lamp produces a continuum of radiation, some of which will be absorbed by molecular species within the atom cell. The amount of atomic absorption observed using the deuterium lamp is negligible and hence the atomic absorption signal is obtained by subtracting the absorbance of the continuum lamp from the total analyte absorbance of the HCL. The deuterium or hydrogen lamp is of most value at wavelengths in the UV region ($< 350\text{ nm}$). The Zeeman effect background correction system is more versatile. It relies on a strong magnetic field operating at approximately 1 T and $50\text{--}60\text{ Hz}$, placed either around the light source or, more commonly, around the atom cell to split the signal into a number of components. The π component is at the normal analyte wavelength; the σ components are typically of 0.01 nm (depending on the strength of the magnetic field) on either side of the π component and hence lie outside the atomic absorption profile. Background can be corrected by subtracting the absorbance with the magnetic field ‘on’, from the signal with the magnet ‘off’. It should be noted that this is a simplified description of the process, as different elements have different splitting patterns and the magnetic field may be applied

longitudinally or transversely, which may also produce different splitting patterns.

When utilizing the Smith–Hieftje system, the HCL is boosted periodically to a much higher current, causing the lamp to ‘self-absorb’. In this state no atomic absorption occurs in the atom cell but the molecular absorption still remains. Background correction is achieved automatically by subtracting the signal obtained at high current from that obtained using the normal current. The process is particularly efficient at removing interferences such as that caused by phosphate or selenium determinations, although the high currents used may shorten the lifetime of the lamp. In modern instruments, modulation of the source is achieved electronically. This enables discrimination between absorption and emission signals. Previously, a rotating sector, often referred to as a ‘chopper’, placed between the source and the atom cell was used.

Single-Beam and Double-Beam Instruments

The vast majority of instruments used for atomic absorption measurements have a single-beam configuration, using the optical layout shown in **Figure 3a**. The double-beam arrangement (**Figure 3b**) is far more complex and offers far fewer advantages for atomic absorption when compared with double-beam spectrometers in molecular spectroscopy. This is because the reference beam does not pass through the atom cell. Despite this, double-beam instruments can compensate for source drift and for warm-up and source noise.

Line Isolation Devices

To ensure that only light of a wavelength specific to the analyte of interest is being measured, a line isolation device is required. Until recently, the line isolation device used for atomic absorption was a monochromator. There are numerous types of monochromator, but

Figure 3 Schematics of (a) single-beam and (b) double-beam spectrometers. Reproduced from Ebdon L (1998) *Introduction to Analytical Atomic Spectrometry*, with permission from Wiley.

modern instruments typically use one of three designs: Ebert, Czerny–Turner or Littrow configuration. These are shown schematically in Figure 4.

Light of all wavelengths enters the monochromator through an entrance slit and is then split into specific wavelengths using either a prism, or more commonly, a diffraction grating. By altering the position of this dispersing element, light of only the desired wavelength passes through the exit slit to the detector. Since the method of atomic absorption is so specific, very highly resolving monochromators are not required. Thus, the focal length of an atomic absorption monochromator is often 0.25 or 0.5 m compared with a minimum of 0.75 m required for conventional optical emission spectroscopy.

A monochromator enables only one wavelength to be interrogated at any instant; this was something of a weakness of atomic absorption spectroscopy. New technology, however, has enabled the development of multi-element spectrometers that use a bank of between 4 and 6 HCLs and an echelle-style polychromator employing orders of 100 or more and are thus capable of considerable dispersion. In addition, such instruments have no exit slit, and so a huge number of wavelengths may be focused onto an array detector such as a charge-coupled device. A schematic diagram of such an instrument is shown in Figure 5. Research continues into producing a continuum light source that would enable 30–40 analytes to be determined simultaneously.

Detection Systems

Traditionally, detection of the light isolated by the monochromator has been accomplished using a

Figure 4 Schematics of different monochromator types: (a) Ebert, (b) Czerny–Turner, (c) Littrow. Reproduced from Ebdon L (1998) *Introduction to Analytical Atomic Spectrometry*, with permission from Wiley.

Figure 5 Echelle-based polychromator.

photomultiplier tube (PMT). Several configurations exist, for example end-on and side-on, and the construction may be of different materials, to increase the efficiency at different wavelengths; but basically they all work in a similar way. Light enters the multiplier through a quartz window and impacts with a photocathode that is usually made from one of a number of alloys (e.g. Cs-Sb, Na-K-Sb-Cs or Ga-As), which then emits electrons. These electrons are then accelerated down a series of dynodes, each being at a more positive potential than the previous one. As the electrons impact with successive dynodes, further electrons are ejected and hence a cascade effect occurs. In this way a single photon may cause the ejection of 10^6 electrons. The number of electrons is then measured at the anode and the resulting current is proportional to the radiation reaching the PMT.

As described previously, a number of different materials may be used to coat the photocathode in the PMT, and each has a different response curve. Some, for example the Cs-Sb tube, have very little sensitivity above 600 nm, but others, for example Ga-As, may be used up to almost 900 nm. The response profiles of some commonly used photomultipliers are shown in **Figure 6**.

Conventional spectrometers use a detector that is capable of measuring only one signal. Multielement instruments use state-of-the-art diode arrays or charge-coupled devices that can measure numerous spatially

separated signals and can therefore simultaneously determine the signals arising from a bank of HCLs. A charge-coupled device may be considered to be similar to an electronic photographic plate. The device consists of several hundred linear photodetector arrays on a silicon chip with dimensions of typically 13×18 mm. The line isolation device (often an echelle grating) separates the analytical wavelengths, and these may then be detected on different regions of the array. A detailed description of how the array works is beyond the scope of this text.

Instrument Control and Output Devices

Manual controls and dials have slowly disappeared, with the large majority of modern instruments being controlled by computer. In addition to controlling the instrumental parameters, the computer may be used to programme autosamplers, save experimental parameters and data, calibrate with known standards, plot calibration curves, use scale expansion facilities (if necessary) and produce statistical data from the results. A continuous graphics mode enables the signal to be monitored over a period of time. This is especially useful when flow injection, chromatography or hydride-generation transients are to be detected and integrated. Older instrumentation relied on a chart recorder for the same purpose.

Sample Introduction and Atom Cells

For flame systems, the sample is introduced via a nebulizer and spray chamber assembly. Sample is drawn up the intake capillary by the Venturi effect. The liquid sample column comes into contact with the fast moving flame gases and is shattered into small droplets. In many systems it is further smashed into still smaller droplets by an impact bead. The flame gases then carry the aerosol (the nebular) through a spray chamber containing a series of baffles or flow spoilers. These act as a droplet size filter, passing the larger droplets to waste (85–90% of the sample) and allowing the finer droplets to be transported to the flame. For electrothermal atomizers, the sample is placed into the atom cell either using a hand-held micropipette or by an autosampler. Since most instruments are supplied with an autosampler and the precision associated with their use is superior to that of the micropipette, most laboratories make use of this method of sample introduction.

As described previously, there are two basic types of atom cell—flame and electrothermal tube—but both can have numerous modifications. The flame cell most commonly used is the 10 cm length air–acetylene burner. This provides a flame that is at approximately 2300°C (although the actual temperature will depend on the

Figure 6 Response curves for several commercial photomultiplier tubes. Reproduced from Ebdon L (1998) *Introduction to Analytical Atomic Spectrometry*, with permission from Wiley.

fuel/air ratio). The flame may be used in a fuel-lean mode, which produces a hot, oxidizing blue flame; in a fuel-rich mode, which produces a cooler, reducing yellow flame; or in a stoichiometric mode whose properties are between the two. Different analytes give different sensitivities depending on the flame type. Chromium, for instance, gives better sensitivity in a reducing flame, whereas for magnesium it is better to use a lean, oxidizing flame.

Different areas of the flame have different temperatures and different chemical properties. The efficiency of atomization of analytes will therefore depend critically on the area within the flame. Hence, it is important that the light beam from the HCL passes through the region of the flame where atomization is optimal. Optimization of the burner height is therefore necessary to ensure that maximum sensitivity is achieved.

Although an air-acetylene flame is sufficient for the atomization of the majority of analytes, it is not sufficiently hot or reducing to atomize analytes that form refractory oxides (e.g. Al, Mo, Si and Ti). For analytes such as these, a nitrous oxide-acetylene flame of length 5 cm is used. This flame is hotter (2900 °C) and contains typically 2.5–3.0 times as much fuel as the air-acetylene flame. Other flame types, for example air-propane and air-hydrogen also exist, although they are less commonly used. The air-hydrogen flame (2200 °C) is almost invisible and has the advantage of being transparent at lower wavelengths offering improved noise characteristics for elements such as lead or tin at around 220 nm. The inhomogeneity of flame chemistry and the need for burner height optimization hold true for all flame types.

One common modification to a flame cell is to place a quartz tube on the burner head so that the light beam passes through the length of the tube. This method is especially useful when using sample introduction by hydride generation or by gas chromatography. The tube is heated either by a flame or electrically using a wire winding. The analyte, which enters the tube via a hole or slit cut into the side, is atomized within the tube. The atoms then leave the tube but, because of their retention in the tube, spend longer in the light beam than in normal flame systems. An increase in sensitivity is therefore obtained. Another small modification of this system is that, instead of a quartz tube, a quartz T-piece may be used. However, the function is the same.

Electrothermal atom cells have changed radically since their inception in the late 1950s. The majority of electrothermal devices have been based on graphite tubes that are heated electrically (resistively) from either end. Modifications such as the West Rod Atomizer (a carbon filament) were also devised but were later abandoned. Tubes and filaments made from highly refractory metals such as tungsten and tantalum have also been made, but they tend to become brittle and distorted after extended

use and have poor resistance to some acids. Their use continues, however, in some laboratories that need to determine carbide-forming elements. For example, silicon reacts with the graphite tube to form silicon carbide, which is both very refractory and very stable. The silicon is therefore not atomized and is lost analytically. Use of a metal vaporizer prevents this.

In electrothermal atomization the sample is introduced into the tube, which is then heated in a series of steps at increasing temperature. The sample is dried at a temperature just above the boiling point of the solvent (but not so hot as to cause frothing and spitting of the sample); ashed (charred at an intermediate temperature to remove as much of the concomitant matrix and potential interferences as possible without losing any analyte); and then atomized at a high temperature. During the atomization stage, the atoms leave the graphite surface and enter the light beam, where they absorb the incident radiation. The ashing and atomizing temperatures used will depend on the analyte of interest; for example, some analytes such as lead are relatively volatile and so cannot be ashed at temperatures above 450 °C, otherwise volatile salts such as chlorides will be lost. Other analytes, for example, magnesium, are less volatile and can be ashed at temperatures close to 1000 °C without analyte loss. Such elements require a much higher atomization temperature. The sensitivity of ETAAS is greater than that for FAAS because the atoms are formed within the confines of a tube and hence spend longer time in the light beam. Also, since the sample is placed within the atom cell, 100% of it is available for analysis compared with the 10–15% available in flame systems. A comparison of characteristic concentrations (concentration that gives an absorbance of 0.0044) obtained for flame and electrothermal techniques for many analytes is shown in **Table 1**. It must be stressed that the figures for ETAAS will depend critically on the injection volume and so values tend to be given in absolute terms (i.e. a weight).

Overall, the Massmann design of electrothermal atomizer in which the tube is heated from either end is still the most common (**Figure 7b**), but more recently transversely heated tubes have been developed (**Figure 7a**). The longitudinally heated tubes have a temperature gradient along the tube, with the central portion being several hundred degrees hotter than the ends. This can lead to condensation of analyte at the cooler ends and subsequent reatomization from the hot graphite surface. Several atomization peaks may therefore result. The transversely heated tubes do not have a temperature gradient and therefore do not suffer from this problem.

Interferences

Flame techniques are regarded as being relatively free from interferences, but some distinct classes of

interference do exist. These include a few spectral interferences (e.g. Eu at 324.753 nm on Cu at 324.754 nm), ionization interferences and chemical interferences. Ionization interference is a vapour-phase interference (in the past often termed cation enhancement) that occurs when the sample contains large amounts of an easily ionized element. The presence of large concentrations of easily ionized elements will lead to a large concentration of electrons in the flame. These electrons prevent the ionization of the analyte and hence lead to higher atomic absorption signals. If the easily ionized element is not present in the standards, the analyte may be partially ionized (and lost analytically) and hence serious overestimates of the true concentration will be obtained. This type of interference may be overcome by adding an excess of easily ionized element to all standards and samples.

Figure 7 Electrothermal tubes available commercially: (a) transversely heated graphite atomizer (THGA), (b) longitudinally heated Massmann atomizer. Reproduced from Ebdon L (1998) *Introduction to Analytical Atomic Spectrometry*, with permission from Wiley.

Chemical interferences may exist in several different forms:

- Formation of less volatile compounds, for example when phosphate is present during the determination of calcium. Calcium phosphate is refractory and hence atomization will be retarded in comparison with calcium in the standards.
- Formation of more volatile compounds, for example chlorides.
- Occlusion into refractory compounds. Small amounts of analyte may become trapped in a refractory substance and hence not be atomized efficiently.
- Occlusion into volatile compounds. Some compounds sublime explosively and hence atomization may be enhanced.

Most of these interferences may be overcome by using a hotter flame (e.g. nitrous oxide-acetylene); by adding a chelating reagent (e.g. EDTA) to complex preferentially with the analyte; by adding a releasing agent (e.g. lanthanum) that will combine preferentially with phosphate; or by optimizing the flame conditions and viewing height.

ETAAS was renowned for being highly prone to interferences. However, modern methods and instrumentation have decreased this problem substantially. Interferences include memory effects, chemical interferences (loss of analyte as a volatile salt, carbide formation, condensation and recombination), background absorption (smoke) and physical interferences such as those resulting from placing the sample on a different part of the tube. The stabilized temperature platform furnace (STPF) concept has gone a long way in eliminating the problem. The concept is that a 'matrix modifier' is required for interference-free determinations. This is a material that either decreases the volatility of the analyte, enabling higher ash temperatures to be achieved and hence boiling away more interference (a common example is a mix of palladium and magnesium nitrates) or increases the volatility of the matrix (for example, the introduction of air 'burns away' many interferences leaving the analytes in the atomizer). The matrix modifier may be placed in the autosampler and added to all samples and standards. Other requirements for the STPF concept include a rapid heating rate during atomization, integrated signals (rather than peak height), a powerful background correction system (e.g. Zeeman), fast electronics to measure the transient signal, and isothermal operation. Isothermal operation means that the analyte is vaporized from the graphite surface into hot gas. In normal ETAAS, the analyte leaves the hot tube wall and enters the cooler gas phase. Under these circumstances it may recombine with some other species to form a compound and thus be lost analytically. To overcome this, platforms that are only loosely in contact with the tube walls have been developed. The analytes in this case are atomized not by the resistively heated graphite tube but by the surrounding gas. The transversely heated tubes described earlier have a platform as an integral part of the tube. A modification to this technique, called probe atomization, has also been developed. Here the sample is placed on a probe and is then dried and ashed in the normal way. The probe is then removed from the tube, which is heated to the atomization temperature. The probe is then reintroduced into the hot environment.

Most analytical techniques for use with furnace work now utilize the advantages of the STPF concept. Other interferences, for example formation of carbides, may be partially overcome by treating the atomizer with a carbide-forming element, such as by soaking in tantalum solution. The principle is that the tantalum occupies the active sites on the surface, thereby preventing the analyte from forming a carbide.

Methods

Numerous methods have been described for use with AAS, but the majority require the sample to be in a liquid

form. Some ETAAS systems allow the analysis of solids directly (e.g. by weighing small amounts onto sampling boats that may be slotted into specialized tubes), but usually, if solids are to be analysed, acid decomposition methods are required. An alternative is the analysis of slurries, using finely ground material ($<10\ \mu\text{m}$) dispersed in a solvent. Manual agitation of the slurry ensures homogeneity of the sample, enabling a representative aliquot to be introduced. Some autosamplers come equipped with an ultrasonic agitator that will perform the same task. This method of analysis is frequently used in ETAAS.

If samples containing high levels of dissolved (or suspended) solids are to be analysed by FAAS, a flow injection technique (in which discrete aliquots of sample are introduced) may be used. This has also been referred to as 'gulp sampling'. This prevents salting up of the nebulizer and blockage of the burner slot, which are obviously undesirable effects that have an adverse effect on sensitivity and signal stability. Flow injection techniques may also be used to preconcentrate analytes. If the sample flows through a column containing an ion-exchange resin, the analytes will be retained. Elution with a small volume of acid may yield very high preconcentration factors. This technique has been used for both FAAS and, more recently, for ETAAS, yielding limits of detection far superior to those achieved under normal conditions. A typical flow injection manifold suitable for this type of application is shown in **Figure 8**.

A more traditional method of preconcentration is solvent extraction. FAAS may be used as a detector for analytes in organic solvents (sensitivity may even be improved because of improved nebulization efficiency), but occasional blocking of the burner slot by carbon may occur. This may be removed by gentle rubbing with a noncombustible material (such as a spatula). Organic solvents may also be introduced to ETAAS, but the 'dry'-stage temperature has to be modified to prevent sample loss by spitting.

Hydride generation is a common method for the detection of metalloids such as As, Bi, Ge, Pb, Sb, Se, Sn and Te, although other vapours, for example Hg or alkylated Cd, may also be determined. This technique improves the sensitivity of the analysis substantially. Since the sample is in the gas phase, the sample transport

Figure 8 Typical flow injection manifold for matrix analyte preconcentration or matrix elimination.

efficiency is close to 100%. The hydrides atomize readily in the flame, although this approach is usually used in conjunction with a quartz T-piece in the atom cell. Methods have been developed that trap the hydrides on the surface of a graphite tube for use with ETAAS. This leads to preconcentration and further improvements in detection limit.

Chromatography has been coupled to AAS to effect speciation analysis. Here different chemical forms of an analyte are separated (either by high-performance liquid chromatography (HPLC) or, if they are sufficiently volatile, by gas chromatography) prior to introduction to the atomic absorption instrument. Gas chromatography is usually coupled directly with a T-piece interface arrangement, but HPLC couplings introduce the sample through the conventional nebulizer/spray chamber assembly. A small postcolumn air bleed may be necessary to compensate for the differences in flow rate between the chromatograph ($1\text{--}2\text{ ml min}^{-1}$) and the uptake rate of the nebulizer ($5\text{--}10\text{ ml min}^{-1}$). Chromatography is not frequently coupled with ETAAS because the atom cell is not well suited to continuous monitoring.

The limited linear range offered by the AAS technique may be partially overcome by using alternative, less sensitive lines. This is a useful technique that avoids the requirement to dilute samples. Care must be taken, however, to ensure that viscosity effects do not cause a difference in nebulization efficiency between samples and standards. Alternatively, burner head rotation may be used. This shortens the path in the flame through which the light beam travels and hence decreases sensitivity. However, there is often an increase in noise as a result of using this approach.

Conclusions

The sensitivity offered by the various techniques utilizing AAS for the determination of metals and metalloids is often sufficient for many applications. Direct aspiration of samples in solution into a flame atomic absorption instrument provides the analyst with rapid acquisition of data with good precision. The technique is remarkably

free from interferences and those that do exist may usually be overcome by judicious choice of operating conditions. The instrumentation involved is relatively simple and, for flame work, analyses may easily be performed by nonexpert operators. If increased sensitivity is required, the analyst has the option of preconcentrating the analyte using one of a number of methods prior to introduction to FAAS, or alternatively may use ETAAS. The latter technique, however, does require more experience if reliable results are to be obtained.

A potential disadvantage of using atomic absorption is that in the past instruments have been capable of determining only one analyte at a time. Modern instrumentation has improved this number to as many as six, although it must be stressed that compromise conditions (e.g. in ETAAS temperature programmes) must be used. This may lead to a decrease in overall sensitivity compared with single-element determinations. However, the ongoing development of multielement AAS will certainly boost the use of this already popular and versatile technique.

Atomic absorption spectroscopy (AAS) is a technique for quantitative determination of metals and metalloids by conversion of a sample to atomic vapour and measurement of absorption at a wavelength specific to the element of interest. Owing to high sensitivity and selectivity, the technique is widely used for fundamental studies in physics and physical chemistry: measurements of oscillator strengths, diffusion coefficients of gas phase species, partial pressure of vapours, rate constants of homogeneous and heterogeneous reactions, etc. The widest application of AAS, however, is in analytical chemistry. Nowadays it is one of the most popular techniques for trace analysis of over 65 elements in practically all types of samples (environmental, biological, industrial, etc.).

The vast majority of substances to be analysed by AAS are in the condensed phase. At the same time, atomic absorption, like any other atomic spectrometry technique, can only detect free atoms that are in the gas phase. Thus, any analyte initially present in solution at a concentration $c(\text{liq})$ must first be transferred into the gas phase via the atomization process to produce $N(\text{g})$ free atoms any an atomizer volume. The analyte atoms are then detected by absorption of radiation from a primary source at a wavelength characteristic of the element resulting in an absorption signal, A . Thus, the general scheme of AAS can be presented as follows:

The primary goal of the theory of AAS is to establish the relationship between the measured analytical signal, atomic absorbance, A , and the analyte concentration, c , in the sample. Theoretical description of the two stages involves entirely different sciences: theory of atomization

is based on thermodynamics, kinetics and molecular physics, while description of absorbances is based on optics and spectroscopy. The two stages will be considered separately.

Atom Production

In the first step of an AA determination, the element of interest must be atomized. The ideal atomizer would provide complete atomization of the element irrespective of the sample matrix producing a well-defined and reproducible absorption layer of the analyte atoms. Excitation processes, however, should be minimal so that analyte and background emission noise is small. For achieving the best detection limits, the analyte vapour should not be highly diluted by the atomizer gas. Various types of electric discharges, laser radiation, electron bombardment and inductively coupled plasmas were tested as atomizers. Although not ideal, high-temperature flames and electrothermal atomizers have gained acceptance as the most common technique of atom production in AAS.

Flame Atomization

The longest practiced technique for converting a sample into atoms is the spraying of a sample solution into a combustion flame. The most popular flames used in AAS are the air-C₂H₂ flame providing a maximum temperature of approximately 2500 K and the N₂O-C₂H₂ flame with a maximum temperature exceeding 3000 K. Atomization occurs because of the high enthalpy and temperature of the flame, and through chemical effects. Owing to the generation of cyanogen radicals, which are known to be an efficient scavenger for oxygen, the nitrous oxide-acetylene flame provides not only a hotter but also a more reducing environment for atom production: the lack of oxygen moves equilibria such as $\text{MeO} \rightleftharpoons \text{Me} + \text{O}$ to the right. Therefore an N₂O-C₂H₂ flame provides greater atomization efficiencies and thus better detection limits for refractory elements, such as Al, Ta, Ti, Zr, Si, V and the rare earths.

Atom production in flames is an extremely complex process consisting of many stages and involving numerous side processes. A quantitative theory of analyte atomization in flames is absent. Qualitatively, the process can be described as follows: the solution droplets sprayed into the flame are first dried, the resulting solid micro-particles become molten and vaporize or thermally decompose to produce gaseous molecules that are finally dissociated into free atoms. The atoms may further be excited and ionized and form new compounds. These processes are dependent upon the temperature and the reducing power of the flame and occur within a few milliseconds – the time required by the sample to pass

through the flame. The processes taking place in flames are shown in more detail in **Figure 1**.

Electrothermal Atomization

In the majority of cases this occurs in a small graphite tube where the sample to be analysed is introduced via a small aperture in the upper tube wall. Metals such as tantalum or tungsten are also used to construct electrothermal atomizers as well as nontubular structures for the atomizer (graphite cups, rods, filaments, etc.). After a 5–50 µl droplet of the sample solution has been deposited into the graphite furnace, it is heated resistively through a series of preprogrammed temperature stages to provide (1) drying of the droplet to evaporate the solvent (~370 K for approximately 30 s); (2) thermal pretreatment (pyrolysis) to remove volatiles without loss of analyte (600–1500 K for 45 s) (this allows selective volatilization of matrix components that are purged from the atomizer by a flow of inert gas); (3) analyte atomization (1500–3000 K achieved rapidly at a heating rate of approximately 2000 K s⁻¹). A major difference of electrothermal atomization from atomization in flames is that some matrix components are removed at the pyrolysis step and the atomization takes place within a confined geometry in an inert gas atmosphere. During atomization, the purge gas flow is shut off so that analyte atoms remain in the probing beam as long as possible.

The number of analyte atoms in the atomizer volume $N(t)$, generated during the atomization stage is described by the convolution

$$N(t) = \int_0^t S(t')R(t, t')dt' \quad [1]$$

Here *the supply function* $S(t')$, gives the rate (atoms s⁻¹) of the primary generation of analyte atoms from the deposited sample, whereas *the removal function*, $R(t, t')$ characterizes the subsequent transfer of the vaporized atoms in the atomizer volume. In the simplest case of vaporization of a monolayer of atoms from the atomizer surface the supply function is given as:

$$S(t) = N_0\nu \exp\left\{-\frac{E}{RT(t)} - \nu \int_0^t \exp\left[-\frac{E}{RT(t')}\right]dt'\right\} \quad [2]$$

where N_0 is the total number of atoms in the deposited sample, ν and E are the frequency factor and the activation energy of the vaporization process, respectively, R is the gas constant and $T(t)$ is the time-dependent atomizer temperature. A typical example of the supply function in electrothermal AAS is given in **Figure 2**. The removal function $R(t, t')$ gives the probability of an analyte atom, vaporized at the time, t' , to be present in the atomizer

production and thin arrangement. Weinheim: VCH.

volume at a later instant, $t > t'$. Early in time, the probability is equal to unity and decreases with increasing time because of loss processes. Generally, the loss processes include concentration and thermodiffusion, and convection. The knowledge of the removal function allows calculation of the mean residence time, τ , of analyte in the atomizer volume. This parameter is defined as $\tau = \int_0^\infty R(t) dt$ and gives the lifetime of evaporated atoms in the atomizer volume. When the analyte loss is governed only by concentration diffusion through the tube ends, the residence time can be estimated by the following relationship:

[3]

where L is the tube length, a is the linear dimension of the area occupied by the sample on the atomizer surface, and D

is the analyte diffusion coefficient. Typically, the analyte residence time in tube graphite atomizers is a few tenths of a second, which is about 100 times longer than in a flame. The long residence time, along with the high degree of analyte atomization caused by the reducing environment, leads to a 10- to 1000-fold increase in graphite furnace sensitivity compared with flame AAS.

The typical change in the total number of analyte atoms, $N(t)$, in the tube electrothermal atomizer obtained by convolution [1] of the supply function with the diffusion removal function is given in **Figure 2**.

The actual atom production and dissipation processes in electrothermal atomizer are much more complex than that described in the preceding text. In many cases the analyte is atomized as a result of a set of multistage processes taking place simultaneously. The basic processes that occur with analyte in a graphite furnace

Figure 2 Supply function $S(t)$ of silver atoms computed for the change in the atomizer temperature $T(t)$ ($E = 280 \text{ kJ mol}^{-1}$, $v = 10^{13} \text{ s}^{-1}$); the change in the total number of silver atoms within the atomizer volume $N(t)$.

are shown schematically in **Figure 3** and listed in **Table 1**. The last column of the table shows the elements for which the respective processes have been documented.

In addition to the widely used atomization techniques, mention must also be made of 'the hydride generation technique'. The method is based on conversion of a hydride forming element (As, Bi, Ge, Sb, Se, Sn, Te) in an acidified sample to a volatile hydride and transport of the released hydride to an atomizer (hydrogen diffuse flame, graphite furnace, heated quartz tube) where it is

atomized to give free analyte atoms. Sodium borohydride is almost exclusively used as an agent for conversion of analyte to hydride

where El is the element of interest and m may or may not equal n . The advantage of sample volatilization as a gaseous hydride lies in the analyte's preconcentration and separation from the sample matrix. This results in an enhanced sensitivity and in a significant reduction of interferences during atomization. The main disadvantages of the method are interferences by substances in the solution that reduce the efficiency of hydride generation.

Relative detection limits achieved by the described atomization techniques are presented in **Table 2**.

Atomic Absorption

AAS is based on the interaction of the probing radiation beam from a primary source with gas phase analyte atoms. Two different types of primary source are used in AAS: line sources emitting narrow spectral lines of the element to be analysed and a continuum source (normally a high-pressure xenon arc lamp) that produces radiation from below 180 nm to over 800 nm. In principle, the continuum source is best suited for AAS. It has a unique capability for multielement determinations, and provides extended analytical range and inherent background correction.

However, the lack of intensity found below 280 nm still limits the use of the source in research laboratories. In conventional AAS, the line radiation of the element of interest is generated in a hollow-cathode lamp (HCL) or an electrodeless discharge lamp (EDL). The spectral profile, $J(\lambda)$, of the analytical line emitted by the source interacts with the absorption profile, $k(\lambda)$, of the analyte atoms in the atomizer (**Figure 4**). It is seen that radiation absorption is strongly dependent on the shape and relative position of the two spectral profiles. To quantitatively describe absorption, both emission and absorption profiles must first be well defined.

**Figure 4** Schematic diagram of the emission $J(\lambda)$ and absorption $k(\lambda)$ spectral profiles typical in AAS.

Emission and Absorption Line Profiles

Three major broadening mechanisms determine emission and absorption profiles in AAS: the Doppler effect, interatomic collisions and hyperfine splitting. Other types of broadening (natural broadening and Stark broadening) are negligible. The Doppler broadening originates from the thermal agitation of emitting and absorbing atoms that results in a Gaussian-shaped spectral line (curve G in **Figure 5**). The full width, $\Delta\nu_D$, at one-half of the maximum intensity (FWHM) of the Doppler-broadened atomic line is given by

$$\Delta\nu_D = \frac{7.16}{\lambda} \sqrt{\frac{T}{M}} \quad [4]$$

where $\Delta\nu_D$ is in cm^{-1} , λ in nm, T in K and M in g mol^{-1} . The width is inversely proportional to the wavelength of the transition, to the square root of the absolute temperature, T , and to the reciprocal of the square root of the molecular weight of the analyte, M . The absorption line widths predicted from this equation range from 1 pm to 10 pm for flame and electrothermal atomizers. The Doppler widths of the lines emitted by HCLs and EDLs are 2–3 times lower than those for absorption profiles in atomizers.

The second major broadening mechanism in AAS is collision or pressure broadening which originates from deactivation of the excited state due to interatomic collisions. There are two types of collisions. Collisions between two analyte atoms lead to resonance broadening which is negligible in analytical AAS because the analyte

Figure 5 Normalized theoretical Gaussian (G), Lorentzian (L) and Voigt (V) line profiles versus dimensionless frequency. The FWHMs and areas of the Gaussian and Lorentzian peaks are equal; the Voigt profile is the convolution of the (G) and (L) profiles.

concentration is small. However, Lorentz broadening, which involves collisions between analyte atoms and foreign species (Ar atoms in electrothermal atomizers) called perturbers, are significant. Compared to a Doppler spectral profile, the Lorentzian profile is broader, has a lower peak height and is described by a Lorentzian function f (curve L in **Figure 5**) with the FWHM given by

$$\Delta\nu_L = N_p \sigma \sqrt{\frac{8RT}{\pi} \left(\frac{1}{M_A} + \frac{1}{M_p} \right)} \quad [5]$$

Here N_p is the number density of perturbers (cm^{-3}), σ is the collisional cross section (cm^2), M_A and M_p are the molecular weight (g mol^{-1}) of the analyte and the perturbers, respectively. The collision width predicted by eqn [5] for absorption profiles is about the same order of magnitude as the Doppler line width (1–10 pm). The $\Delta\nu_L$ values for lines emitted by the HCLs and EDLs are much lower than those for the absorption profiles in atomizers because of low pressure in the primary sources. Therefore this part of the broadening is normally neglected in the sources. However, at high optical densities of an absorbing layer when the wings of the emission line play an important role, the Lorentzian component in the broadening of the emission line also becomes important. In addition to broadening the lines, collisions also cause a small shift in the line centre (towards the longer wavelengths in an Ar environment) and an asymmetry in the far line wings. The shift is proportional to the collision

width and theory predicts a value of 2.76 for the width-to-shift ratio (it is shown schematically in **Figure 4**).

The total spectral profile of an atomic line is given by the convolution of the Gaussian profile (due to Doppler broadening) and the Lorentzian profile (due to pressure broadening). The result is the Voigt function (curve V in **Figure 5**), $H(\omega, a)$:

$$H(\omega, a) = \frac{a}{\pi} \int_{-\infty}^{\infty} \frac{e^{-y^2}}{a^2 + (\omega - y)^2} dy \quad [6]$$

where $a = \sqrt{\ln 2} (\Delta\nu_L/\Delta\nu_D)$ is the damping constant determining the shape of the Voigt profile: as the damping constant increases, the profile broadens and its peak height decreases. In the extreme cases of $a=0$ and $a=\infty$, the Voigt function goes to the purely Gaussian function and purely Lorentzian function, respectively. Normally, a dimensionless frequency, ω , normalized by the Doppler width $\Delta\nu_D$ of the absorption profile is used for computations: $\omega = (\nu/\Delta\nu_D)2\sqrt{\ln 2}$. Within about 1% accuracy, the FWHM of the Voigt profile can be estimated from the following empirical equation:

$$\Delta\nu_V = \frac{\Delta\nu_L}{2} \sqrt{\left[\left(\frac{\Delta\nu_L}{2} \right)^2 + (\Delta\nu_D)^2 \right]} \quad [7]$$

Finally, the third broadening mechanism is hyperfine splitting which is caused by isotope shifts and nuclear spin splitting. Generally a spectral line consists of n hyperfine components with relative intensities, b_p ($\sum_{i=1}^n b_i = 1$) that are located at a distance $\Delta\omega_i$ from the component with the minimum frequency. Each component is Doppler and collision broadened and described by the Voigt function [6]. Thus in the general case the emission $J(\omega)$ and absorption $k(\omega)$ profiles are presented as follows:

$$J(\omega) = \sum_{i=1}^n b_i H_i \left(\frac{\omega - \Delta\omega_i}{\alpha}; a_e \right),$$

$$k(\omega) = \sum_{j=1}^n b_j H_j (\omega - \Delta\omega_j + \Delta\omega_S; a) \quad [8]$$

where α is the ratio of the Doppler width of the emission line to the Doppler width of the absorption line. The equation takes into account that the emission profile, $J(\omega)$, is approximately $1/\alpha$ times narrower than the absorption profile, $k(\omega)$, in the scale of dimensionless frequency ω and that the absorption profile, is pressure-shifted relative to the emission profile to a value $\Delta\omega_S$. For many analytical lines used in AAS the hyperfine splitting is greater than Doppler and pressure broadening and determines the total FWHM.

Figure 6 Emission $J(\lambda)$ and absorption $k(\lambda)$ spectral profiles of the 283.3 nm lead resonance line computed for the conditions of graphite furnace AAS ($a_e = 0.01$, $a = 1.24$; $T = 2100$ K). $J_{tr}(\lambda)$ is the emission profile that is transmitted through a uniform layer of $3 \times 10^{12} \text{ cm}^{-2}$ lead atoms.

In graphite furnace AAS, the damping constant, a , varies from 0.17 (Be resonance line, 234.9 nm) to 3.27 (Cs, 852.1 nm) for absorption lines and its value for emission lines, a_e , in the primary sources varies from 0.01 to 0.05. A relatively small value of the a -parameter means that the emission profile is primarily determined by the Doppler broadening.

Figure 6 shows the emission and absorption spectral profiles of the lead 283.3 nm resonance line computed for the conditions of graphite furnace AAS using eqn [8]. The line consists of five hyperfine components that are clearly seen in the emission profile. Because of higher temperature and much higher pressure, the absorption profile is wider and shifted towards the longer wavelengths.

Calibration Curve Shapes

It has been demonstrated that in AAS the atomization efficiency is close to 100% for the majority of elements in aqueous solutions. Assuming complete atomization, the shape of calibration curves in AAS is determined by the dependence of detected atomic absorbance on the number of absorbing atoms. The relationship $A = f(N)$ is called the *concentration curve* and its description is one of the primary goals of theoretical AAS.

The phenomenon of radiation absorption had already been studied quantitatively early in the 18th century, mainly on liquids and crystals. The investigations resulted in the Beer–Lambert law relating the radiant flux, Φ_{tr} , transmitted through an absorbing layer to the optical

properties of the layer. In modern formulation, the law applied to a spatially uniform absorbing layer of length l and a uniform parallel probing beam is written as follows:

$$\Phi_{tr}(\lambda) = \Phi_0(\lambda) \exp[-\mu(\lambda)l] \quad [9]$$

where $\Phi_0(\lambda)$ is the incident radiant flux incident at a wavelength λ , $\mu(\lambda)$ is a wavelength-dependent attenuation coefficient which is the sum of absorption, $k(\lambda)$, and scattering, $\varepsilon(\lambda)$, coefficients: $\mu(\lambda) = k(\lambda) + \varepsilon(\lambda)$. Curve $J_{tr}(\lambda)$ in **Figure 6** shows the spectral profile of the lead 283.3 nm resonance line that is transmitted through a uniform layer of $3 \times 10^{12} \text{ cm}^{-2}$ lead atoms. It was assumed that the spatially uniform incident radiation with the spectral profile $J(\lambda)$ is absorbed by the absorption profile $k(\lambda)$, without scattering, following eqn [9]. Generally, a nonuniform radiation with intensity distribution $J(x, y)$ over the beam cross section is used to probe a non-uniform layer of absorbing species with the number density $n(x, y, z)$. With non-uniform probing beams, a radiant flux passing through a surface S within a spectral bandwidth $\{-\lambda^*, \lambda^*\}$ is expressed in terms of intensities as follows:

$$\Phi = \int_S \int_{-\lambda^*}^{\lambda^*} J(x, y) J(\lambda) dx dy d\lambda$$

where $J(\lambda)$ is a function describing the spectral composition of the radiation.

Absorbance, A , which is the analytical signal in AAS, is defined as the logarithm of the ratio of the incident radiant flux, Φ_0 , to the radiant flux, Φ_{tr} , that is transmitted through the absorbing layer of the analyte atoms. Using the Beer–Lambert law [9] for expressing the transmitted radiant flux, the general relationship for the absorbance recorded by an AA spectrometer can be expressed as follows:

$$A = \log \frac{\Phi_0}{\Phi_{tr}} = \log \left\{ \frac{\int_0^b \int_0^b \int_{-\lambda^*}^{\lambda^*} J(x, y) J(\lambda) d\lambda dx dy}{\int_0^b \int_0^b \int_{-\lambda^*}^{\lambda^*} J(x, y) J(\lambda) \exp\left(-\int_0^l k(\lambda; x, y, z) dz\right) d\lambda dx dy} \right\} \quad [10]$$

Here, b and b are the width and the height of the monochromator entrance slit, l is the length of the absorbing layer; the limits of $-\lambda^*$ to λ^* are the spectral bandwidth isolated by the monochromator. It was assumed that radiation attenuation occurs only because of atomic absorption, that is $\varepsilon(\lambda) = 0$. The absorption coefficient, $k(\lambda; x, y, z)$, depends on the number density of absorbing atoms in the ground state, n_0 (cm^{-3}), and the

spectral profile, $k(\lambda)$, of the absorption line, and is presented as

$$k(\lambda; x, y, z) = \frac{2\sqrt{\pi \ln 2} e^2}{mc} \cdot \frac{f}{\Delta \nu_D} \cdot n_0(x, y, z) k(\lambda) = c(\lambda, T) n_0(x, y, z) \quad [11]$$

Here e and m are the charge and mass of the electron, respectively, c is the velocity of light, f is the oscillator strength of the spectral transition, $\Delta \nu_D$ is the Doppler width of the absorption line. The coefficient $c(\lambda, T)$ denotes the combination of values that depend only on the spectral features of the analysis lines.

The general relationship [10] is simplified significantly if the following assumptions are made: (1) radial distributions of the probing beam and the analyte atoms are uniform, that is $J(x, y) = \text{const}$, $n(x, y, z) = n(z)$; (2) the atomizer is spatially isothermal, that is $T(x, y, z) = \text{const}$ and (3) the emission line is a single and infinitely narrow line at λ_0 so that it is described by Dirac's delta-function: $J(\lambda) = J_0 \delta(\lambda - \lambda_0)$. Substitution of these simplifications into eqn [10] gives

$$A = (\log e) \int_0^l k(z; \lambda_0) dz = (\log e) c(\lambda_0, T) N \quad [12]$$

where $c(\lambda_0, T)$ is a constant for given transition and for a given temperature, $N(\text{cm}^{-2}) = \int_0^l n(z) dz$ is the number of absorbing atoms per unit cross sectional area along the radiation beam; in the case of uniform analyte distributions, this value is proportional to the total number of analyte atoms in the atomizer. Thus, if assumptions mentioned in the preceding text are valid, the recorded absorbance is proportional to the total number of absorbing atoms in the atomizer and the concentration curve $A = f(N)$ is a straight line. This is a basis for AAS to be an analytical technique, because the recorded signal, A , is directly proportional to the unknown number, N , of analyte atoms. Such a concentration curve computed for the case of a lead resonance line is presented by curve 1 in **Figure 7**.

The actual situation, however, differs substantially from that presented by simple eqn [12]. It follows from general relationship [10] that absorbance is dependent on three groups of factors: (1) the spectral characteristics of the analysis line (dependence of J and k on λ); (2) the cross sectional distribution of intensity in the incident beam, $J(x, y)$; and (3) spatial distribution of the analyte and temperature within the atomizer (dependence of k on x, y, z). Thus detected absorbance, A , depends not only on the number, N , of absorbing atoms but also on the spectral features of the analysis lines used to probe the absorbing layer and the spatial distribution of analyte atoms and radiation intensity in the

Figure 7 The evolution of the 283.3 nm lead concentration curve as the spectral and spatial features are successively taken into account. Emission line is: single and infinitely narrow (1); single and broadened (2); all the spectral features of the line are taken into account including hyperfine splitting and the pressure shift (3); (4) as (3) plus absorbing layer is assumed to be nonuniform in the radial cross section with the analyte number density at the atomizer bottom 4 times greater than that in the upper part of the absorbing layer.

probing beam:

$$A = f(N; \text{Spectral, Spatial}) \quad [13]$$

The effect of spectral features of the analysis line and spatial non-uniformities of the absorbing layer is illustrated in **Figure 7**. Curve 2 is the lead concentration curve when the resonance line is assumed to be a single but broadened one; accounting for all the spectral features of the emission and absorption profiles, including hyperfine structure and pressure shift, results in curve 3. It can be seen that broadening of the analysis line lead to a bending of the concentration curve and decreasing of its slope, the major effect being the hyperfine broadening. Additional accounting for the fact that the analyte is distributed non-uniformly in the atomizer cross section leads to further curvature and a decrease in the slope of concentration curve (curve 4). **Figure 7** illustrates clearly the importance of the *spectral* and *spatial* features in relationship [10]. Research shows, however, that these undesirable dependencies can be avoided if transmitted intensities are measured with spectral, spatial and temporal resolutions. The *multidimensional* absorbance detected in such a way is dependent only on the number of absorbing atoms irrespective of their spatial distribution and spectral features of the primary source.

Interferences

An interference effect is a change of the analytical signal by the sample matrix as compared to the reference standard, typically an acidified aqueous solution. There are two types of interference in spectrochemical analysis, *spectral* and *non-spectral*. Spectral interference originates from incomplete isolation of the radiation emitted or absorbed by the analyte from other radiation detected by the spectrometer. Any reasons other than specific atomic absorption that cause radiation attenuation in eqn [9] result in spectral interferences. They arise from absorption of radiation by overlapping molecular bands or atomic lines of concomitants; scattering of source radiation by non-volatilized microparticles (smoke, salt particles, condensed microdrops); and foreign line absorption if the corresponding radiation happens to be emitted by the radiation source, in addition to the analysis line, within the spectral bandwidth of the monochromator. The first two sources of spectral interferences are most common and described as background attenuation or background absorption. In general, they are more pronounced at shorter wavelengths. Most background attenuation can be distinguished from the analyte absorption because the element only absorbs in the very narrow spectral region while the background attenuation is less specific and extends over a considerably broader wavelength band. Instrumental methods of correction for background attenuation effects include compensation using a continuum source and the Zeeman effect.

For interferences other than spectral, the analyte itself is directly affected. The non-spectral interferences are best classified according to the stage at which the particular interference occurs, that is solute-volatilization and vapour-phase interferences. A non-spectral interference is found when the analyte exhibits a different sensitivity in the presence of sample concomitants as compared to the analyte in a reference solution. The difference in the signal may be due to analyte loss during the thermal pretreatment stage in the electrothermal atomizer; analyte reaction with concomitants in the condensed phase to form compounds that are atomized to a lesser extent; analyte ionization or change in the degree of ionization caused by concomitants.

Reactions of the analyte with the tube material (graphite) or the purge gas are not normally considered to be interferences because they influence the analyte in the sample and in the standard to the same degree. A non-spectral interference is in many instances best detected by the use of the analyte addition technique. An interference exists if the slope of the additions curve is different from that of the calibration curve. For most systems, non-spectral interferences in electrothermal AAS can be effectively eliminated by adding a proper matrix modifier ($\text{Pd-Mg(NO}_3)_2$ is the most common modifier) that delays analyte volatilization until the atomizer temperature is sufficiently high and steady for efficient atomization, and buffers the gas phase composition.

Like all atomic spectroscopic techniques, emission spectroscopy and fluorescence spectroscopy require the production of free atoms (or ions) in the gaseous phase for detection. These two techniques require population of a particular excited electronic state and the concentration is determined by monitoring the radiative relaxation process, that is, detection of the photon produced. In general, the intensity of the light emitted should be proportional to the gas phase atom density and, ultimately, to the concentration of the analyte atoms in the sample being introduced to the atomization source. Likewise, it follows that increasing the excited state population will enhance the sensitivity of the method.

The difference in the two spectroscopic approaches stems from the means by which the excited state is populated. In fluorescence, absorption of radiation at the proper frequency is used for excitation, whereas in emission spectroscopy, collisional energy transfer with other atoms, molecules, ions, or electrons produces the excited state population.

Atomic Emission

Atomic emission for spectrochemical analysis is the oldest of modern atomic spectroscopic techniques. Although excitation by combustion flames and electrical arcs were methods of choice in the early days of spectrochemical analysis and have been replaced generally by modern plasmas, flames are still routinely used for group I and II determinations, and high-voltage sparks still find niche applications in, for example, metallurgical industries. Modern plasmas, especially inductively coupled plasmas (ICPs), are the dominant excitation source in today's laboratories and provide detection capabilities in the range of parts per billion to subparts per billion for many metals. With modern detectors (e.g., charge-coupled devices (CCDs)), simultaneous multielement detection is also easily accomplished, and the dynamic

range can easily cover 4–5 orders of magnitude in concentration for any given element. In short, quantitative determinations for most of the elements in the periodic table can be performed with modern emission techniques and require only a few minutes per sample once calibration curves have been established. Applications span the range from ultratrace analysis to the determination of minor and even major elemental components of a sample. Rapid, sensitive analyses with precisions that can be less than $\pm 1\%$ are characteristic of modern emission spectroscopy, which is the workhorse in many laboratories where elemental analyses are conducted.

Other emission sources are also commercially available, two of which address direct analysis of solids, that is, no sample dissolution necessary. These are laser-induced breakdown spectroscopy (LIBS) and glow discharge spectroscopy. Further details of such techniques can be found in other articles in this encyclopedia via the 'See also' list.

Excited State Population

Since excited state populations are achieved by collisions with other charged or neutral particles within the source, the population of any given excited state can be calculated if a local thermodynamic equilibrium (LTE) can be assumed to exist within the source. Under LTE, the fractional population of any given excited electronic state N_j can be given by

$$\frac{N_j}{N_{\text{total}}} = \frac{g_j \exp(-E_j/kT)}{Z(T)} \quad [1]$$

where g_j and E_j are the statistical weight and excitation energy of the j th state, respectively; k is Boltzmann's constant and T the temperature (in kelvin). $Z(T)$, the partition function, is the 'sum over states' or simply represents the relative population of all other states in the atom:

$$Z(T) = \sum_{i=0}^{\infty} g_i \exp\left(\frac{-E_i}{kT}\right) \quad [2]$$

For relatively cool sources (e.g., $T < 3000$ K), $Z(T)$ can be approximated by the value for the statistical weight of the ground state, g_0 , which implies that a majority of the atoms are present in the ground state ($E_0 = 0$). For hotter sources, such as the ICP, accurate calculation of the partition function requires consideration of excited states and can be

tedious. The tedium can be avoided by referring to a publication by de Galan et al., in which polynomial coefficients for the calculation of partition functions for neutral and singly ionized elements are tabulated for temperatures ranging between 1500 and 7000 K.

Although an elevated population of the excited state is a *necessary condition* to realize a strong emission signal and good analytical sensitivity, it is not a *sufficient condition*. It is also necessary that there exists a high probability that once populated, the excited state will *radiatively relax* to a lower energy state. In many instances, the transition used terminates in the ground state of the atom or ion, and the line emitted is termed the resonance line. The probability that radiative relaxation will occur is indicated by the magnitude of the *oscillator strength* (f) or Einstein A coefficient for spontaneous emission. Both of these parameters are indicators of the strength of the emission, with smaller values indicative of low probability or even ‘forbidden’ transitions. Examples of where such transitions might have a low probability include transitions where an apparent change in electron spin state is needed to accomplish the relaxation, that is, ‘spin-forbidden’ transition. As a result of selection rules, which dictate the likelihood of transitions occurring, not all possible transitions from an excited state to a lower lying state occur with equal probabilities. In spite of this, the emission spectrum of elements with d or f electrons can exhibit hundreds to thousands of lines in the UV and visible region of the spectrum.

Some of the principles governing the formation of an emission spectrum are illustrated in the partial energy level diagram for the neutral sodium atom shown in **Figure 1**. In a hot flame or plasma that is in thermal equilibrium, the upper levels of the atoms are populated by collisions to a degree described by eqn [1]. Excited atoms return to the ground state by one of several possible relaxation pathways, a few of which are illustrated in the figure. Each radiative transition between two atomic states produces a photon with a wavelength that is inversely proportional to the energy difference between the two levels. Not all possible transitions between levels occur. For example, the transition between levels a and b in **Figure 1** is an example of a ‘forbidden’ transition mentioned in the foregoing paragraph. The transitions producing photons at 330.4 and 589.6 nm are examples of resonance transitions. Of the transitions shown in the figure, the one at 589.6 nm would produce the most intense emission in a flame or plasma because it has a high probability for radiative relaxation and its low excitation energy leads to large population compared to other excited states.

Numerous compilations of atomic spectra have been published. The most comprehensive and readily accessible collection of atomic spectral data is maintained by NIST and is available on the Web.

Figure 1 Partial energy level diagram for the neutral sodium atom.

Line Widths

Although radiative relaxation can produce relatively narrow spectral lines (e.g., 0.001 nm or less, depending on the source and line), they are not truly monochromatic. At the very least, each spectral line exhibits a ‘natural line width’ that is governed by Heisenberg’s uncertainty principle:

$$\Delta E \tau_r = \frac{b}{2\pi} \quad [3]$$

where ΔE is the uncertainty in the position of the state, τ_r the excited state lifetime (typically 1–10 ns), and b Planck’s constant. With rearrangement and substitution of Planck’s relationship ($E = h\nu$), the natural line width in hertz (Hz) can be expressed as

$$\Delta \nu_N = \frac{1}{2\pi\tau_r} = \frac{A_{ji}}{2\pi} \quad [4]$$

where A_{ji} is the Einstein A coefficient for spontaneous emission from the j th to the i th state. With typical excited state lifetimes of approximately 10 ns, the natural line widths are of the order of 0.000 01 nm.

Line widths in most sources are generally broader than the natural line widths as a result of collisional and Doppler broadening. Collisional broadening is a result of collisions or near collisions between the excited state

atom or ion and other particles in the system that result in a perturbation of the relative location of the energy states of the atom at the time of emission. As a result, elevated pressures and temperatures in the source enhance the impact of collisional broadening on the line width. Doppler broadening is a consequence of phenomena similar to the familiar Doppler effect for sound, which results in a change in pitch or frequency as a sound-emitting source approaches and then passes an observer, for example, a passing train that is blowing its whistle. In a similar fashion, an emitting atom that is moving toward or away from the observer produces a frequency shift in the emitted radiation that is related to the relative direction and velocity of the emitter. Taken over an ensemble of atoms moving in random directions, this produces a broadened spectral line. Like collisional broadening, this is accentuated with increasing temperatures since the average molecular velocities increase with temperature. For sources at atmospheric pressure and temperatures of a few thousand degrees, these broadening events are similar in magnitude and produce spectral line widths in the range of 0.001–0.01 nm.

Other effects that can produce broadening or splitting of the spectral lines include Stark broadening and Zeeman splitting. The former results from local electric fields from neighboring ions and electrons or from externally applied strong electrical fields. The latter results from the interaction of a magnetic field with the particles or ions.

From eqn [1], it is apparent that elevated temperatures promote population of electronic excited states. However, competing with this enhanced excited state population is ionization.

This is an equilibrium condition and can be expressed by the Saha equation:

$$K_i = \frac{n_{M^+} n_e}{n_M} \quad [6]$$

where n represents the number density of the respective species. This equilibrium is quantitatively described by

$$\log K_i = 15.68 + \log \frac{Z_{M^+}}{Z_M} + 1.5 \log T - \frac{540 E_{i\text{on}}}{T} \quad [7]$$

where Z represents the partition functions for the respective species and $E_{i\text{on}}$ is the ionization potential in electron volts (eV). Equations [1] and [7] combined provide a comprehensive description of a system of atoms in equilibrium. The Boltzmann equation describes the distribution among possible states for a given stage of ionization, whereas the Saha equation describes the equilibrium between adjacent stages of ionization. Each stage of ionization has associated with it a unique set of

energy levels and emission lines associated with transitions among those levels.

In high-temperature sources, atoms from multiple stages of ionization can be radiating simultaneously, resulting in complex emission spectra. To minimize confusion, an atomic line should be identified with at least three pieces of information: the emitting element, the stage of ionization, and the wavelength. The stages of ionization are indicated with roman numerals, starting with I for the neutral atom, II for the singly charged ion, and so on. For example, one of the pair of yellow emission lines from a sodium street lamp comes from the neutral atom and would be designated Na I 589.6 nm. One of the strong lines from singly charged calcium ions in an ICP has the designation Ca II 393.4 nm.

A practical consequence of the Saha equilibrium among ionization states is that, in hot sources, the number densities of ions may exceed those of the neutral atoms. The most intense radiation comes from ionic lines, making those lines the first choice for sensitive analytical measurements.

Although the earlier discussion applies to many analytical atomic spectroscopic sources, much of the discussion and quantitative treatments require the existence of LTE. Some sources do not exist at LTE. Typically, sources that are at reduced pressure, which limits the rate of collisional energy distribution, or those where energy is being input at a rapidly changing rate may not exhibit LTE. As an example, glow discharge sources such as hollow cathode lamps used in atomic absorption are operated in a low-pressure noble gas environment and exhibit extremely high ionization temperatures but very low kinetic gas temperatures; that is, the temperatures are not equal, and as a result, the system is not considered at LTE. Hollow cathode lamps, in spite of their kinetic gas temperature of only a few hundred degrees, exhibit an extremely high degree of ionization and population of some very high-energy excited states.

Calibration Curves

In general, the intensity of light emitted from the excitation source should be proportional to the concentration of analyte atoms or ions within the source. This linear relationship should be valid as long as equilibrium processes within the source govern the fraction of the total analyte population in the excited state that is producing the emission. An example of where this may not be true can be seen in eqns [5]–[7], where the degree of ionization is dependent on the partial pressure of the free atomic species. In the case of a flame source, low concentrations of easily ionized elements (e.g., alkali metals) show measurably higher degrees of ionization than high concentrations. As a result, curvature at the low-concentration end of the calibration curve can exist. Interestingly, the much hotter

Figure 2 Intensity profiles with increasing analyte concentrations for an atomic emission line subject to self-absorption.

ICP does not exhibit the same nonlinearity at low concentrations. This is a result of the nearly constant electron density (n_e) from the argon support gas, which keeps the degree of ionization of the analyte nearly independent of its concentration.

Since resonance lines are often used for spectrochemical analysis, radiation emitted from the center of an excitation source may pass through a substantial concentration of atoms *in the ground state* in the outer regions of the source. As a consequence, some of this light may be absorbed by the analyte atoms in this region. This is referred to as *self-absorption*. In the extreme, the absorbing atoms can reduce the intensity at the central wavelength of the emitting line to near zero (i.e., *self-reversal*). **Figure 2** shows intensity profiles with increasing analyte concentrations for an atomic emission line subject to self-absorption.

Consider light emitted from the hot central region of a source (e.g., a flame) at an intensity of $I_{c,\lambda}^0$. The intensity is a function of both the analyte concentration and the wavelength, with maximum intensity emitted at the line center.

$$I_{c,\lambda}^0 = k'_\lambda c \quad [8]$$

where k'_λ includes a function that defines the line profile. As detailed previously, the width and the shape of the function depend on the local temperature and pressure in the source. The resonance emission also passes through the cooler outer regions of the source that also contain analyte atoms. However, they are emitting a negligible amount of light because of the cooler temperatures and the very strong temperature dependence of emission (eqn [1]). Thus, these cooler atoms can absorb the resonance radiation without contributing significantly to the emission intensity. The absorption of this resonance radiation exhibits a Beer's law-type behavior, where the intensity passing through this layer is related to the concentration c and the incident intensity $I_{c,\lambda}^0$:

$$I_{c,\lambda} = I_{c,\lambda}^0 \exp(-k''_\lambda c) \quad [9]$$

Figure 3 Graphical representation of the wavelength dependence of k' and k'' .

where k''_λ is indicative of the strength of the absorption at any given λ . A graphical representation of the wavelength dependence of k' and k'' is shown in **Figure 3**. (Note: The scale for k'' has been reversed for clearer presentation.) Since $I_{c,\lambda}^0$ is dependent on c (eqn [8]), the intensity emitted from the source *after passing through this absorbing layer* can be described as

$$I_c = \int k'_\lambda c \exp(-k''_\lambda c) \partial \lambda \quad [10]$$

From this expression, two things become apparent: (1) the intensity detected (I_c) is *not* linearly dependent on c unless $0 \leq k''_\lambda \ll 1$ (i.e., there is a low probability of absorbing a photon) or c is very small, and (2) as c increases, the deviation from the ideal calibration curve slope of k' increases. This behavior generates nonlinear calibration curves with the greatest curvature at higher concentrations. The degree to which self-absorption affects calibration curves is strongly dependent on the geometry of the source and on temperature distributions in it. The effect is most pronounced when emission from a hot region in the source must pass through a cooler region before it is detected. Such a situation arises in hollow cathode lamps and dc arcs. Self-absorption is less of a problem in sources such as the ICP where the temperature is uniform across the source. Other instrumental factors (e.g., stray light in the spectrometer) can also impact the shape of the calibration curve but will not be dealt with here.

Atomic Fluorescence

Atomic fluorescence spectrometry (AFS) is used primarily as a diagnostic tool for the study of flames and plasmas, where its combination of selectivity and sensitivity allows investigators to measure the density of a selected atomic or ionic state. The use of this technique for routine analysis has been limited because competing techniques, most notably ICP mass spectrometry, provide comparable sensitivity and much greater versatility with simpler instrumentation. One exception is the use of atomic fluorescence for the determination of mercury. Because mercury atomic vapor can be easily generated at room temperature, dedicated Hg detectors based on AFS are relatively simple and are capable of achieving subparts per trillion detection limits.

Excited State Population

Fluorescence, like emission, relies on radiative relaxation of an atom or ion from an excited electronic state to a lower lying state. Unlike emission spectroscopy, population of the excited state occurs via absorption of a photon. Two possible fluorescence schemes are shown in **Figure 4**. If the excitation beam that is absorbed is the same as the detected fluorescent wavelength, it is termed resonance fluorescence. Nonresonance fluorescence denotes the case where the excitation and fluorescence wavelengths are different. The latter excitation/detection approach offers the advantage of allowing scattered radiation from the excitation beam to be easily separated from the fluorescence. Additionally, by using a non-resonance line for analysis, self-absorption by the source of the fluorescence signal is minimized. (See also the discussion in the following section 'Calibration curves'.)

If the relaxation is a spontaneous emission process occurring after photon absorption has populated the excited state, then it follows that the intensity of the detected radiation will increase for transitions with larger Einstein A coefficients, as in emission spectroscopy.

However, population of the excited state is not governed by thermal or collisional processes, but instead by absorption of a photon of the proper frequency. Thus, it is logical that improved absorption should also yield improved sensitivity.

Absorption is a *stimulated* event; that is, the number of atoms that are promoted to a higher energy level is dependent not only on the total number of atoms in the low-lying originating state which are capable of absorbing a photon but also on the photon flux. For example, if one were to double the incident excitation beam intensity, it would be expected that twice as many atoms will absorb photons. (Note: This implies that the fraction of the total photons absorbed by the analyte is constant, which is consistent with the precepts of absorption where the ratio of I^0/I is independent of I^0 .) This dependence on the incident photon flux makes the absorption a *stimulated process*, and the probability of absorbing a photon is governed by the magnitude of the Einstein B coefficient for stimulated absorption. This B coefficient is proportional to the Einstein A coefficient and to f , the oscillator strength. Hence, a justification for the axiom that 'a strong emitter is a strong absorber' is often cited in atomic spectroscopy.

Since sensitivity is dependent on the excitation source intensity, it would seem that one should be able to increase the source intensity and continually improve the sensitivity of the fluorescence technique for analysis. This is valid with low radiative fluxes. However, there is one more interaction between radiation and matter that must be introduced into this discussion to explain the limitation of this assumption: *stimulated emission*.

Stimulated emission is the process that occurs when an atom or ion (or molecule, for that matter) is in an excited state, and a photon interacts with this atom to stimulate the relaxation to a lower energy state (where $\Delta E = h\nu$). The stimulated photon is emitted at the same wavelength as the incident photon, travels in the same direction as the incident photon, and is in phase with the incident photon. As a result of this process, the excited

Figure 4 Two possible fluorescence schemes.

state has been *diminished* by this interaction with light. Since this is a stimulated process (like absorption), the number of particles that will participate in this interaction will depend on the incident flux and the number of atoms or ions located in the proper excited state. In short, as the excitation source intensity continues to increase, the population of the excited state increases from stimulated absorption *and* the number of stimulated emission events also increases as the excited state population increases. Eventually, a point is reached where the rate of the stimulated absorption equals the rate of the stimulated emission and no net increase (or decrease) in population of the excited state occurs. The system is said to be 'saturated.' Additional increases in the incident radiation source intensity have little impact on either the fraction of atoms or ions in the excited state or the spontaneous emission, that is, fluorescence signal. As a result, small fluctuations in the source light intensity do not alter the detected signal for a given concentration of atoms in the atomization cell, for example, flame and ICP. Usually, source intensities comparable to those produced by lasers are needed to reach saturation.

The fluorescence schemes illustrated in **Figure 4** unrealistically suggest that there is only one or two possible wavelengths for spontaneous emission from an excited level. In most cases, there will be multiple relaxation pathways and multiple fluorescence lines. The relative intensities of the lines will be governed by the relative magnitudes of the transitions' A coefficients. This 'branching' of the fluorescence divides the signal among multiple wavelengths and decreases the signal magnitude on any one line. Fluorescence offers potential sensitivity advantages over emission because, with the right excitation source, it is possible to create much higher populations of excited states than can be created by collisions in a thermal environment. At saturation, the fraction of atoms in an excited state is governed by the statistical weights of the upper and lower levels and often exceeds 50%.

It is also noteworthy that for both atomic emission and fluorescence spectroscopy, a single atom or ion can produce multiple signal photons. The number produced depends on the time an atom resides in a viewing zone and the rate at which it cycles between the lower and upper states. In the case of resonance fluorescence and a strong transition, that rate can be millions of times per second. An atom passing through a laser beam can produce bursts of thousands of fluorescence photons, making the detection of single atoms possible.

Intense laser sources enable a variety of experiments that are impractical with noncoherent sources. For example, two-color (or multiphoton) experiments can also be conducted where multiple-step excitation is the objective. Similar to nonresonance fluorescence discussed previously, multiphoton excitation also makes the

fluorescent transition energy distinctively different from the excitation energy *and* minimizes self-absorption if the terminating level of the fluorescent wavelength is not the ground state. (See the discussion in the following section 'Calibration curves'.)

In many practical atom reservoirs, excited atoms can relax to lower levels by collisional processes that do not produce fluorescence photons. The competition between collisional and radiative processes is an important factor in determining the sensitivity of a fluorescence measurement. The fraction of atoms that emit a fluorescence photon after absorbing a pump photon is referred to as the quantum yield, Φ . In low-pressure sources with low collision rates, quantum yields are close to 1. In atmospheric-pressure flames, where collisions with small molecules effectively quench excited states, quantum yields can be very low.

Line Widths

Parameters discussed previously for line broadening in emission spectrometry are also applicable for fluorescence spectrometry, especially since many of the same atom producers (e.g., flames and ICPs) are used for both techniques. In fluorescence, the width of the absorption profile can be as critical as that of the fluorescent line profile. This is particularly true when a narrow-band excitation source (e.g., lasers or low-pressure discharge lamps) is employed. As the atomic cloud becomes less transparent, the intensity of the excitation beam that reaches the 'analytical volume' in the source center also decreases since it is being attenuated by passing through absorbing atoms in the outer regions of the atomization source. The intensity distribution of this exciting beam is, of course, moderated by k'_λ . Narrow absorption line profiles and narrow excitation line widths (e.g., lasers and low-pressure discharge lamps) accentuate the impact that this absorption has on the fluorescent intensity.

Calibration Curves

As in emission spectrometry, the intensity of the detected radiation should be proportional to the concentration in the original sample, and this is generally true at low concentrations. Like emission, curvature at low concentrations can occur as a result of ionization interferences in some sources for the more easily ionized elements.

Also similar to emission spectrometry, self-absorption (and self-reversal) of the fluorescent spectral lines can also take place within the sample 'cell' *if* a resonance line is the one being monitored and detected and the atom density is sufficiently large. This alone can lead to a flattening of the calibration curve at elevated concentrations, as observed with emission spectroscopy. In addition, if the excitation beam is also a narrow line source used at a resonance wavelength of the analyte, the

excitation beam intensity can be attenuated. This leads to lower populations of the excited state and decreased fluorescence signals when the beam attenuation becomes significant. In fact, with some combinations of excitation source characteristics and analyte absorption line profiles, the calibration curve can roll over at high analyte concentrations, that is, exhibit a negative slope.

Atomic emission spectroscopy is one of the most useful and commonly used techniques for analyses of metals and non-metals providing rapid, sensitive results for analytes in a wide variety of sample matrices. Elements in a sample are excited during their residence in an analytical plasma, and the light emitted from these excited atoms and ions is then collected, separated and detected to produce an emission spectrum. The instrumental components which comprise an atomic emission system include (1) an excitation source, (2) a spectrometer, (3) a detector, and (4) some form of signal and data processing. The methods discussed will include (1) sample introduction, (2) line selection and (3) spectral interferences and correction techniques.

Atomic Emission Sources

The atomic emission source provides for sample vaporization, dissociation and excitation. The ideal excitation source will allow the excitation of all lines of interest for the elements in the sample, and does this reproducibly over enough time to encompass full elemental excitation. Excitation sources include but are not limited to (1) inductively coupled plasma (ICP), (2) direct current plasma (DCP), (3) microwave-induced plasma (MIP) and (4) capacitively coupled microwave plasma (CMP). Glow discharges are utilized for direct solids analyses, but will not be discussed here. An analytical plasma is a high-energy, slightly ionized gas (approximately 0.01–0.1% ionized).

Inductively Coupled Plasmas

The most commonly used ion source for plasma spectrometry, the ICP, is produced by flowing an inert gas,

typically argon, through a water-cooled induction coil which has a high-frequency field (typically 27 MHz) running through it (**Figure 1**). The alternating current in the coil has associated with it a changing magnetic field which induces a changing electric field. The flowing gas is seeded with electrons by means of a Tesla coil. These electrons undergo acceleration by the electric field, and gain the energy necessary to excite and ionize the gaseous atoms by collision. This produces the plasma, self-sustaining as long as the RF and gas flows continue.

Sample particles entering the plasma undergo desolvation, dissociation, atomization and excitation. The ICP has sufficiently long residence times and high enough temperatures so that the sample solvent is completely vaporized, and the analyte reduced to free atoms, which undergo excitation. This excitation results in the emission of light at specific frequencies for elements in the sample, which is proportional to their concentration. An emission spectrometer separates the frequencies of light into discrete wavelengths, which are unique to given elements in the sample.

Figure 1 Inductively coupled plasma and torch schematic.

Direct Current Plasmas

In a DCP, a dc current passing between two electrodes heats the plasma gas, again typically argon, and produces a discharge. The most common version is the three-electrode system (Figure 2). This system has argon flowing around two graphite anodes and a tungsten cathode to produce the plasma. The sample is introduced between the anodes. Vaporization, atomization, ionization and excitation occur. This technique is more tolerant of samples containing a high proportion of solids than the ICP method. However, it is less efficient due to lower plasma temperatures, and the electrodes need to be replaced frequently.

Microwave-Induced Plasmas

A MIP is an electrodeless discharge generated in a glass or quartz capillary discharge tube, often in a resonant cavity. These tubes generally have an inner diameter of the order of a few millimetres, and the plasma gas is an inert gas such as helium or argon. The resonant cavity which is hollow and of the order of a few centimetres diameter, allows coupling of the microwave power into the plasma gas flowing through the capillary discharge tube. The microwave power supply operates at a frequency of 2.45 GHz. Microwave plasmas can be produced at atmospheric pressure, if the design of the cavity allows. Helium plasmas typically require reduced pressure unless a 'Beenakker cavity' is employed (Figure 3). MIPs use lower power levels (hundreds of watts) than those required by the DCP and ICP. However, due to the

decreased size of the MIP, the power densities produced are comparable. Argon has an ionization potential of 15.75 eV, which is not sufficient in the argon ICP to produce the excitation ionization energy needed to ionize some elements efficiently, such as the non-metals. Helium plasmas are more efficient for these problem elements, as the ionization potential of helium is 24.6 eV. The MIP is not very adept at handling liquid samples due to the low powers employed. However, at higher powers above 500 W similar performance to the ICP may be obtained. The general lack of availability of these sources, as part of commercially available instrumentation, has limited their application and use.

Capacitively Coupled Microwave Plasmas

A CMP is formed using a magnetron to produce microwave energy at 2.45 GHz. This is brought to a hollow coaxial electrode via coaxial waveguides. The microwave power is capacitively coupled into the plasma gas, usually argon or nitrogen, via the electrode. This is an atmospheric pressure source with a small plasma volume. Power levels can range from 10 to 1000 W, with frequencies from 200 kHz to 30 MHz. Unlike other MIPs, the CMP is able to handle greater amounts of solvent. However, the CMP has been found to be easily contaminated due to the microwave energy being conducted through a coaxial waveguide to the electrode, which must be replaced regularly.

Spectrometers

The atomic emission source will produce unstable, excited atoms or ions, which spontaneously return to a lower energy state. The emission spectrum is produced when a photon of energy is generated during this transition. The basic assumption is that the emitted energy is proportional to the concentration of atoms or ions in the

Figure 2 Direct current plasma schematic.

Figure 3 Microwave induced plasma schematic illustrating the 'Beenakker Cavity' design.

sample. The measurement of this energy is performed using the optics of the spectrometer to isolate the characteristic elemental emission wavelengths, and to separate this radiation from the plasma background. The spectrometer will need a high resolving power to be able to separate the lines of interest from the adjacent spectral lines (at least 0.1 nm). The spectrometer consists of (1) a dispersive element, such as a grating, and (2) an image transfer assembly which contains the entrance and exit slits, and mirrors or lenses.

The grating provides dispersion of the wavelength range of interest over a given angular range. Some commonly used grating spectrometers include (1) the Paschen–Runge spectrometer which is used in both sequential and simultaneous instruments and has the advantage of extensive wavelength coverage, (2) the echelle grating spectrometer, with excellent dispersion and resolution with a small footprint and (3) the Ebert and Czerny–Turner spectrometers which are similar except that the latter has two mirrors to the Ebert’s one.

The slit allows a narrow line of light to be isolated. The number of lines will represent the various wavelengths emitted by the plasma, with each line corresponding to the image produced by the spectrometer slit, and each wavelength corresponding to a specific element. There are two slits used: (1) the primary slit through which light enters the spectrometer, and (2) the secondary slit through which light exits, producing a line isolated from the rest of the spectrum. The imaging system consists either of lenses or of concave mirrors.

One of the most useful aspects of atomic emission spectrometry is its capability for multi-element analysis. This can be achieved using either the sequential monochromator, where elements in a sample are quickly read one at a time, or the polychromator which allows the simultaneous measurement of the elements of interest.

Monochromators

Multi-element determinations using a monochromator must be sequential, as the monochromator can observe only one line at a time owing to single secondary slit. The slit can be set to scan the wavelengths, which is slower than in a simultaneous instrument, but allows for the selection of a wider range of wavelengths. A scanning monochromator uses a movable grating to find known individual spectral lines at fixed positions, typically a Czerny–Turner configuration. Although this allows the observance of only one individual wavelength at a time, it also allows all wavelengths in the range of the spectrometer to be observed.

Polychromators

Polychromators have a permanently fixed secondary slit for certain individual wavelengths (individual elements).

Figure 4 Beam path through a polychromator.

Each slit will have its own detector. This allows for truly simultaneous analyses of selected elements, resulting in much quicker analyses than the monochromator for elements that have a slit installed. However, the selection of possible analysis lines is limited. **Figure 4** shows a simplified diagram of the beam path in a polychromator. A polychromator can focus the emission lines on the circumference of the Rowland circle by using concave gratings; typically the Paschen–Runge configuration is used. In summary, the polychromator has a throughput advantage while the sequential scanning monochromator has flexibility as its advantage.

Detectors

Photomultiplier Tubes

A photomultiplier tube (PMT) consists of a photosensitive cathode, several dynodes and a collection anode. The dynodes are responsible for the increase in signal by electron multiplication. PMTs see the elemental line intensity per unit time proportionally with current and have wide dynamic ranges. A PMT, housed in a suitable mechanical movement, can scan the range of wavelengths in a spectrum sequentially, which involves longer analysis times. Alternatively, there can be a series of PMTs, each collecting the signal at discrete wavelengths at its assigned exit slit. Unfortunately, it always takes one PMT for each wavelength of light observed, whether the PMT is fixed or roving. Modern instruments have taken advantage of the advent of multichannel solid-state detectors to provide more flexibility in multielement analyses.

Charge-Coupled and Charge-Injection Devices

The charge-coupled and charge-injection devices (CCD and CID) are solid-state sensors with integrated silicon

circuits. They are similar in that they both collect and store charge generated by the light from the emissions in metal-oxide semiconductor (MOS) capacitors. The amount of charge generated in a charge transfer detector is measured either by moving the charge from the detector element where it is collected to a charge-sensing amplifier (CCD), or by moving it within the detector element and measuring the voltage change induced by this movement (CID). The CCD is susceptible to 'blooming' in the presence of too much light, since there can be an overflow of charge from a full pixel to an adjacent one. CCDs are best used in very sensitive, low light level applications. The CID does not suffer from 'blooming' due to its method of nondestructively measuring the photon-generated charge. The CID allows the monitoring of any wavelength between 165 and 800 nm, whereas the range of the CCD is between 170 and 780 nm.

Methods

Sample Introduction

Sample introduction into the plasma is a critical part of the analytical process in atomic emission spectroscopy (AES). Since the ICP is the most commonly used source, the sample introduction schemes described in the following sections will focus more on it than the other sources mentioned previously. Sample is carried into the plasma at the head of a torch by an inert gas, typically argon, flowing in the central tube at $0.3\text{--}1.5\text{ l min}^{-1}$. The sample may be an aerosol, a thermally or spark generated vapour, or a fine powder. Other approaches may also be taken to facilitate the way the analyte reaches the plasma. These procedures include hydride generation and electrothermal vaporization.

Torches

One of the torch configurations more commonly used with the ICP is shown in **Figure 1**. The plasma torch consists of three concentric quartz tubes through which streams of argon flow. The nebulizer gas which carries the analyte into the plasma, flows in the central tube. The auxiliary gas flows around the central tube and adjusts the position of the plasma relative to the torch. The coolant gas streams tangentially through the outer tube, serving to cool the inside walls and centre of the torch, and stabilizes the plasma.

Nebulizers

The great majority of analyses in ICP AES are carried out on liquid samples. The most convenient method for liquids to be introduced into the gas stream is as an aerosol from a nebulizer. The aerosol may be formed by the action of a high-speed jet across the tip of a small

orifice or by the use of an ultrasonic transducer. A spray chamber is usually placed after the nebulizer to remove some of the larger droplets produced and thereby improves the stability of the spectral emission.

The most commonly used nebulizer designs are pneumatic and ultrasonic, although other types (electrostatic, jet impact and monodispersive generators) have been described. The selection of the appropriate nebulizer depends on the characteristics of the sample: mainly density, viscosity, organic content, total dissolved solids and total sample volume. Additionally, the performance of a particular nebulizer can be described using several attributes such as droplet size distribution, efficiency, stability, response time, tendency to clog and memory effects.

Concentric Nebulizers

Solution sample introduction has been associated with pneumatic nebulizers (concentric and cross-flow) almost universally for routine analysis due to their simplicity and low cost. However, they provide low analyte transport efficiency ($< 5\%$) to the plasma and may be prone to clogging.

The most widely used ICP nebulizer is the one-piece Meinhard concentric nebulizer (**Figure 5a**). It is a general-purpose nebulizer with low tolerance for total dissolved solids, used for applications requiring low nebulizer gas flows. It operates in the free running mode whereby the solutions are drawn up by the pressure drop generated as the nebulizer gas passes through the orifice. The viscosity of the solution and the vertical distance through which the liquid is lifted affect the rate of liquid transfer. Although the concentric nebulizer is easy to use, the transport efficiency is low, owing to the wide range of droplet sizes produced. In addition, nebulizer blockage may occur due to the presence of suspended solids becoming lodged in the narrow, central sample uptake capillary. Filtering or centrifuging the sample may minimize the risk of blockage. If a sample with a high dissolved-solids content dries in the nebulizer, it may also cause nebulizer blockage or interfere with the operation of the nebulizer by decreasing the signal. Frequent cleaning of the nebulizer solves this problem.

Cross-flow Nebulizers

The cross-flow nebulizer shows much of the same general behaviour of the concentric nebulizers. The cross-flow nebulizer is less prone to blockage and salting effects, although they may still occur as the sample solution passes through a capillary. The cross-flow nebulizer operates when a horizontal jet of gas passes across the top of a vertical tube (**Figure 5b**). The reduced pressure that is generated draws the liquid up the tube, where, at the top, it is disrupted into a cloud of fine droplets.

Figure 5 Schematic of the (a) concentric nebulizer, (b) cross-flow nebulizer, and (c) Babington nebulizer.

Babington-type Nebulizer

The Babington nebulizer is designed to allow a film of liquid containing sample to flow over the surface of a sphere (Figure 5c). A gas which is forced through an aperture beneath the film produces the aerosol. This design features the liquid sample flowing freely over a small aperture, rather than passing through a fine capillary, and is therefore more tolerant of high dissolved-solids. This kind of nebulizer can be used to introduce slurries into the system since the delivery of the sample is not constrained by a capillary. However, the Babington-type nebulizer shows extensive memory effects since the solution is allowed to wet the entire face of the sphere. A modification of the design is also in use, whereby the liquid sample passes through a V-groove and a gas is introduced from a small hole in the bottom of the groove. The main advantage of the V-groove nebulizer is its resistance to blockage. However, the design produces aerosol less efficiently, and it is of coarser size distribution than that produced by other concentric nebulizers.

Frit-type Nebulizer

The concentric and cross-flow nebulizers are inefficient at the 1 ml min^{-1} flow rate at which they usually operate,

Figure 6 Glass frit nebulizer schematic. Reprint permission from Ingle JD and Crouch SR (1988) *Spectrochemical Analysis*. Englewood Cliffs, NJ: Prentice Hall.

producing only approximately 1% of droplets of the correct size to pass into the plasma. An alternative design is the frit nebulizer, which produces droplets with a mean size of $1 \mu\text{m}$. The glass frit nebulizer is depicted schematically in Figure 6. The sample flows over the fritted glass disc as the nebulizing gas is passed through the frit. This design provides an excellent fine aerosol, but at the expense of the fritted disc clogging over time. The transport efficiency is very high compared to the pneumatic-type nebulizers but the operation is at flows of $100 \mu\text{l min}^{-1}$ or less.

Ultrasonic Nebulizer

The ultrasonic nebulizer also produces fine aerosol and has a high sample-transport efficiency (Figure 7). The aerosol is generated when the solution is fed to the surface of a piezoelectric transducer which operates at a frequency between 0.2 and 10 MHz. Vibrations of the transducer cause the solution to break into small droplets which are then transported to the plasma. The ultrasonic nebulizer offers highly efficient aerosol production independent of the carrier-gas flow rate. With this nebulizer, more analyte can be transported into the plasma at a lower nebulizer gas flow rate than that seen with pneumatic nebulizers. This increases the sensitivity and improves detection limits since samples have a longer residence time in the plasma. However, the high

Figure 7 Ultrasonic nebulizer schematic. Reprint permission from Ingle JD and Crouch SR (1988) *Spectrochemical Analysis*. Englewood Cliffs, NJ: Prentice Hall.

efficiency also allows more water to enter the plasma, producing a cooling effect, which may decrease analyte ionization. Hence these nebulizers require desolvation to be realistically utilized. Apart from the analytical shortcomings of the ultrasonic nebulizer, the high cost of the commercial systems may be prohibitive.

Electrothermal Vaporization

Electrothermal vaporization can introduce liquid, solid, and gaseous (by trapping) samples to the plasma with high analyte transport efficiency (20–80%) and improved sensitivity over pneumatic nebulization. A small amount (5–100 µl) of sample is deposited into an electrically conductive vapourization cell (**Figure 8**). Initially, a low current is applied to the cell, which causes resistive heating to occur and dries the sample. A high current is then passed for a short time (typically 5 s) to completely vaporize the sample. An optional ‘ashing’ stage may be used to remove some of the matrix prior to the analyte vaporization stage. A stream of argon gas is passed through the unit and carries the sample vapour to the plasma. A variable current supply is required for controlling cell heating, and the sequence of heating steps is carried out using an electronic control system. Electrothermal vaporization allows sample matrix components, including the solvent, to be separated from the analytes of interest through judicious selection of temperature programming steps. This may reduce oxide formation and the number of spectroscopic interferences. Additionally, samples with high salt content and limited volume can be analyzed with electrothermal vaporization.

Hydride Generation

The problems associated with liquid sample introduction, and the inefficiencies in analyte transport can be overcome

Figure 8 Illustration of electrothermal vaporization graphite furnace.

by presenting the sample in a gaseous form to the plasma. Introducing the analyte in a gaseous form eliminates the use of a nebulizer and a spray chamber. It also provides nearly 100% analyte transport efficiency, which subsequently improves the detection limits. Additional benefits include no blockage problems, the possibility of matrix separation and analyte preconcentration, and the absence of water, which reduces the levels of many polyatomic ion species. The hydrides of the elements arsenic, bismuth, germanium, lead, antimony, selenium and tin are easily formed in acidic solutions and are gaseous at room temperature. The most frequently used reaction is

where E is the hydride forming element of interest. **Figure 9** shows an apparatus for hydride generation. It allows the mixing of the sample and the reducing agent, followed by the transport of the volatile analyte species (hydride) by the carrier gas to the plasma.

The gaseous sample introduction line is connected directly to the central tube of the plasma torch, eliminating the need for the conventional nebulizer and spray chamber. Additional equipment to handle gas mixing and dilution at controlled flow rates may be required.

Direct Solids Introduction

Direct insertion of solid samples into the ICP can be used for metal powders, salts and geological samples. The sample is placed on a wire loop or cup made from

Figure 9 Hydride generation apparatus. Reprint permission from Ingle JD and Crouch SR (1988) *Spectrochemical Analysis*. Englewood Cliffs, NJ: Prentice Hall.

graphite, molybdenum, tantalum or tungsten. The probe is then moved along the axis of the torch and closer to the plasma where drying takes place. At the completion of this stage, the device is propelled rapidly into the core of the plasma and measurements of the analytes can be taken.

Line Selection

The choice of which line to use for a given sample type is a difficult one, as most elements have many lines available for analysis. Not only the intensity of the line but also whether the line is free of spectral interferences from both the plasma and other sample constituents should be considered. Additionally, the nature of the emission, atomic or ionic, should be considered. The emission could originate from an excited neutral atom, which is termed an atomic transition, or an excited ionized form of the element, which is called an ionic transition. While analysis of elements undergoing transitions of the ionic type tend to experience fewer consequences due to changes in the plasma operating conditions, there are elements that produce no ionic lines, such as aluminium and boron. There are very good reference books which list tables of spectral lines and are included in the Further reading section. Often modern instrumentation has sufficiently 'intelligent' software to assist the operator with line selection.

Spectral Interferences and Correction Techniques

A spectrometer with good resolution will help greatly in the separation of adjacent lines from the spectral line of

Figure 10 Interelement effects of plutonium on calcium (top) and aluminium (bottom).

interest. The effect of partial overlap can be minimized in some cases with a high-resolution spectrometer, and in other cases, can be overcome using correction techniques.

When the interference is from the plasma emission background, there are background correction options available with most commercial instrumentation. The region adjacent to the line of interest can be monitored and subtracted from the overall intensity of the line. If direct spectral overlap is present and there are no alternative suitable lines, the interelement equivalent concentration (IEC) correction technique can be employed. This is the intensity observed at an analyte wavelength in the presence of 1000 mg l⁻¹ of an interfering species. It is expressed mathematically as

$$\text{IEC} = \left(\frac{I_{\text{init}}}{I_a} \right) \times C_a$$

where the correction is in milligrams of analyte per litre of solution, and I_{init} is the intensity read at the analyte wavelength in the presence of 1000 mg l⁻¹ of the interfering species, I_a is the intensity the instrument will produce for a certain analyte concentration at the analyte wavelength, and C_a is the concentration in mg l⁻¹ used to give I_a . This correction can be applied to all the analytes in a method and some instrument manufacturers' software will automatically perform the necessary corrections. Examples of the effect of 1000 ppm plutonium as the interfering element on calcium and aluminium are shown in **Figure 10**. This shows the subarrays obtained for separate solutions of plutonium, calcium and

Figure 11 Interelement equivalent concentration correction factors for several interfering elements on calcium (top) and aluminium (bottom).

aluminium. Graphical representations of interfering elements on calcium and aluminium are shown in **Figure 11**. These graphs are produced by a program written at Los Alamos National Laboratory by DJ Gerth

and illustrate which interfering elements have the strongest effect on the analytes. The elements with the strongest deviation from the average are those needing the interelement correction.

Introduction

Atomic fluorescence spectroscopy (AFS) has been used for elemental analysis for several decades. It has better sensitivity than many atomic absorption techniques and offers a substantially longer linear range. However, despite these advantages, it has not gained the widespread usage of atomic absorption or emission techniques. The use of AFS has been boosted by the production of specialist equipment that is capable of determining individual analytes at very low concentrations (at the ng l^{-1} level). The analytes have tended to be introduced in a gaseous form and hence sample transport efficiency to the atom cell is very high. This article describes the instrumentation and methods available for AFS, although it should be emphasized that much of the instrumentation associated with this technique is often very similar to that used for atomic absorption spectroscopy (AAS). A schematic diagram of the different parts of an AFS instrument is shown in **Figure 1**. It can be seen that the light source, atom cell, line isolation device, and detector and readout system used for AFS are very similar to those used in AAS, although there may be subtle differences

and the components may be less sophisticated, as described in the following text.

Light Sources

As can be seen from **Figure 1**, light sources for AFS are placed at right angles to the detector. This is to ensure that incidental radiation from the source is not detected. Since a more intense source will lead to greater sensitivity, in AFS a standard hollow cathode lamp (HCL) is often insufficient for the majority of applications. A range of alternatives has therefore been developed. An electrodeless discharge lamp (EDL) is suitable because it has an intensity 200–2000 times greater than that of an HCL. Boosted-discharge hollow cathode lamps (BDHCLs) are similar to standard HCLs but can be operated at greatly increased current. The light output is consequently several times more intense. A similar effect may be obtained by pulsing a standard HCL to 100–1000 mA, although this will reduce the lifetime of the lamp. Continuum sources such as 150–500 W xenon lamps have also been used, but there are several problems associated with their use. The most obvious drawback is the relatively poor intensity offered at each individual wavelength by the blackbody irradiator. The problem is particularly bad in the ultraviolet (UV) region of the spectrum. Scatter has also been reported as being problematic.

Vapor discharge lamps have been available for some elements (e.g., Cd, Ga, Hg, In, K, Na, and Tl) since the inception of commercial instrumentation, although such devices are limited to the volatile elements and are therefore not universal.

Figure 1 A schematic representation of an AFS instrument.

Lasers have the greatest output intensity and would therefore be expected to yield the highest sensitivity. Unfortunately, they are expensive and have, in the past, been produced to give light of very specific wavelengths, which may not correspond to the frequency required to excite the analyte atoms. The development of the tunable dye laser has helped to overcome this problem. Frequency doubling (i.e., halving the wavelength of the light output) has enabled wavelengths well into the UV region to be obtained. A nitrogen laser pump can be used to obtain a wavelength of 220 nm whereas an Nd:YAG (neodymium-yttrium aluminum garnet) laser allows 180 nm to be reached. An added advantage of high-intensity lasers is that they may cause saturation fluorescence (population inversion), which nullifies the effects of quenching and self-absorption. Another source that has been used to initiate fluorescence is an inductively coupled plasma (ICP). This may be used either as a continuum source (if the actual fireball is used) or as a line source (if the tail flame is used). The use of an ICP as a light source to initiate fluorescence is not yet a routine technique.

As with AAS, modulation of the light source enables an optimal signal-to-noise ratio to be obtained. The frequency of modulation depends on the light source, but may be up to 10 kHz for an EDL.

Atom Cell

Several atom cells have been used for AFS. The majority of applications have used a circular flame atom cell (sometimes with a mirror placed to collect as much light as possible), but more recently ICPs and electrothermal atomizers have also been used. There is a risk of self-absorption at high analyte concentrations, that is, light fluoresced by some atoms will be absorbed by others in different parts of the flame. A circular flame has a smaller path length compared with a slot burner, hence its popularity. A variety of fuels have been used for the flames. Air-acetylene, nitrous oxide-acetylene, and argon-hydrogen diffusion flames have all been used successfully. Quenching (the non-radiative loss of energy) increases with increasing flame temperature and so the cooler air-acetylene and hydrogen flames are often used. Conversely, the hot nitrous oxide-acetylene flame aids the atomization of refractory compounds. The quenching cross-section of the colliding particles also affects the amount of quenching. The relative quenching cross-section of the different flame gases increases in the order argon (negligible) < hydrogen (low) < oxygen (high). It can therefore be seen that for easily atomized analytes, an argon-hydrogen diffusion flame offers at the best properties for atomic fluorescence.

ICPs atomize refractory analytes very efficiently because of their high temperature (8000 K), and therefore have a very high fluorescent yield. Care must be taken,

however, to ensure that ionization of the analyte species does not occur. An added advantage is that the plasma is made up of argon and is therefore optically thin (i.e., it has a low quenching cross-section). The disadvantages of using a plasma as the atom cell are that it is more expensive and the instrumentation is more complex. When a plasma is used as an atom cell, the light source may be placed in one of two orientations. It may pass light through the side of the plasma although more recently it has been used axially, that is, the source passes light through the entire length of the plasma. Since the second configuration has a longer path length, more analyte atoms may be excited and hence improved detection limits are obtained. The disadvantage with this configuration is that the light source must be protected in some way from the extreme temperatures of the plasma. This may be achieved by using either a water-cooled condenser containing a quartz window or a protective gas flow to protect the lens from the plasma tail flame. If mirrors or some other collection device are placed around the plasma, then all fluoresced light may be collected and directed to the detector. It has been noted that the optimum viewing height for fluorescence measurements using an ICP as the atom cell occurs substantially higher above the load coil than for emission measurements. Observation above 3 cm is routine and making measurements from the tail flame is common to ensure that a signal above the background and analyte emission noise is obtained. Similarly, a decrease in plasma power has also been found to be beneficial.

Electrothermal atomizers for AFS share many of the advantages associated with their use for AAS. The argon inert gas that prevents oxidation of the graphite tube ensures that minimal quenching occurs, although a number of other interferences may occur. By and large, the interferences are very similar to those experienced in traditional electrothermal AAS, such as carbide formation (for some analytes), scatter by particulate matter, and losses during thermal pretreatment. A more comprehensive overview of interferences may be found in the articles on AAS. The use of matrix modifiers to assist in the separation of the analyte from the matrix is still often necessary.

Where a laser is used as light source, a technique termed laser-induced fluorescence electrothermal atomization (LIF-ETA) is possible. A schematic diagram of a typical LIF-ETA system is shown in **Figure 2(a)**. The light source passes through a pierced mirror and into the atomizer. Light fluoresced from the analytes within the atomizer then reflects off the mirror and onto the detector. An alternative configuration is shown in **Figure 2(b)**, in which the laser irradiates the sample through the injection port. The two configurations are known as longitudinal and transverse geometries, respectively. The technique is capable of extremely low detection limits (below 1 pg g^{-1}) and has therefore found use in the nuclear, biomedical, electronics, and semiconductor industries.

Figure 2 (a) Schematic diagram of longitudinal laser-induced fluorescence with electrothermal atomization. (b) Transverse laser-induced fluorescence. A heated atom cell is not required in the case of mercury determinations. Mercury produces an atomic vapor at room temperature and therefore does not require a flame to cause atomization. Instead, the mercury vapor may simply be transported to an atom cell at room temperature. The radiation from the light source excites the mercury atoms in the normal way.

Line Isolation Devices

A conventional monochromator (Ebert, Czerny–Turner, Littrow, or Echelle) may be used (see AAS articles for details), but some of the more basic instrumentation uses interference filters. These are optical filters that remove large bands of radiation in a nondispersive way. A dispersion element such as a prism or a grating is therefore not required. Only a relatively narrow band of radiation is allowed to pass to the detector. The disadvantage with such devices is that they are not particularly efficient and hence much of the fluoresced light is lost. An alternative development is the multireflectance filter. This is shown diagrammatically in **Figure 3**, and has the advantages of being 80% efficient at transmitting the wavelengths of interest while virtually eliminating background noise. Such a

Figure 3 A multireflectance filter.

device therefore has a superior performance to other wavelength filters.

Interference and multireflectance filters may be used when the analyte of interest has been separated from the matrix and all the concomitant elements. In such a case, the analyte atoms are the only elements that will fluoresce when light from a monochromatic light source is used to

Figure 4 Schematic of a very basic nondispersive AF spectrometer.

excite them. Powerful dispersion gratings are therefore not required because, theoretically, light specific to only one element is produced. A schematic diagram of a very basic instrument that uses a multireflectance filter is shown in **Figure 4**. If other analytes are present in the atom cell, then either a monochromator is required to separate the other wavelengths (produced by emission) or the source must be modulated so that distinction between emission and fluorescence signals may be made.

Detectors

The light isolated by the line isolation device (monochromator, interference filter, or multireflectance filter) is normally detected using a photomultiplier tube (PMT). A description of how these devices work may be found in the articles on AAS. It should be noted that some basic instruments (e.g., as shown in **Figure 4**) often use a solar-blind photomultiplier tube (PMT). This is a PMT that detects radiation in the UV region but does not detect light in the visible region of the spectrum.

Readout and Data-Handling Systems

The readout and data-handling systems used for AFS are similar to those found for AAS instrumentation. The signal from the PMT passes through an amplifier and then on to the readout device. This may be a digital display, a chart recorder, an integrator, or a computer with software dedicated to the instrument. The last alternative is the most commonly used in modern instrumentation. The software is likely to be able to control calibration, plot graphs, perform quality assurance tests, and calculate means and standard deviations of the results. One advantage of using a computer to control the analysis is that the use of an autosampler becomes a possibility. This enables unattended operation of the instrumentation.

Applications

As described previously, although techniques to utilize AFS were developed several decades ago, until recently they were not widely used. However, a new generation of simple AFS instruments has been developed to specifically detect the vapor-forming elements, such as those that form hydrides (As and Se) and mercury, which forms an atomic vapor. All of these analytes have a primary line below 260 nm and, since the analytes may be readily separated from the bulk matrix and concomitant elements, dispersion is not necessary. Instead, these basic instruments originally used a simple interference filter, although these have now been superseded by the more efficient multireflectance filter.

The theory behind hydride generation is beyond the scope of this text, but in brief, if a sample is mixed with a reducing agent, such as sodium tetrahydroborate, then some elements, for example, As, Bi, Ge, Pb, Se, Sb, Sn, and Te, will form hydrides. It must be noted that the efficiency of hydride formation depends on the oxidation state of the analyte. Arsenic(III) forms a hydride more efficiently than As(V), and Se(IV) forms a hydride whereas Se(VI) does not. It is therefore necessary to ensure that all the analyte atoms are in the same oxidation state; this is normally achieved using one of a variety of reducing agents.

Once formed, the hydride leaves the reaction cell and is flushed toward the AFS instrument using an inert gas (usually argon). During this process, hydrogen is formed as a breakdown product of tetrahydroborate, and can be swept along with the hydride in the argon to the atom cell, where it can be used as the fuel for the hydrogen-argon diffusion flame. More hydrogen may be added as necessary from an external source. Since a hydrogen-argon diffusion flame is used, the amount of water entering the flame must be minimal (otherwise quenching and flame instability result). The hydride and water vapor are therefore separated, often by passing through a membrane dryer tube. This is a tube containing a semipermeable hygroscopic membrane surrounded by a counterflow of dry gas. Water vapor in the hydride passes through the membrane and is removed by the counterflow. The dry hydride continues through the tube to be flushed toward the AFS instrument by the flow of argon.

Mercury may be determined using very similar instrumentation, but it may also be introduced in a number of other ways. Since mercury is volatile, solid samples may be placed on a small platform and then heated. The sample is thus vaporized and the vapors are passed through a trap (sand coated with gold). The mercury is trapped onto the gold while the smoke and matrix constituents pass through and are hence separated from the analyte. Heating of the gold trap to 900 °C releases the mercury, which may then be swept in a flow of argon to the AFS instrument. This technique has the advantage that

the mercury may be preconcentrated on the trap, since several repeat samples may be vaporized and the mercury collected before it is subsequently removed from the trap. The use of the gold trap preconcentrator is equally applicable to the analysis of liquid samples. When a gold trap preconcentrator is used, the limit of detection (LOD) for mercury is substantially below 1 ng l^{-1} , which is superior to that obtained using atomic absorption, emission, or inductively coupled plasma–mass spectrometric (ICP-MS) techniques.

The instrumentation described earlier may also be used for speciation studies. In such cases, a separation technique such as high-performance liquid chromatography (HPLC) or gas chromatography (GC) is coupled with the AFS instrument. The chromatography is used to separate different analyte species and some on-line chemistry is subsequently required to convert the species into a chemical form suitable for vapor generation. Although the chemistry behind these methods of speciation is beyond the scope of this text, it should be emphasized that the method used should be powerful enough to convert even very stable species, such as arsenobetaine or selenomethionine into atomic arsenic and selenium. The additional use of photolysis may therefore be necessary. Similarly, pyrolysis may be necessary to convert different mercury species into atomic mercury since this is the only species that will fluoresce.

As described previously, vapor introduction approaches are by far the most common application of atomic fluorescence. Despite this, mention of other methods should be made. If a conventional nebulizer and spray chamber assembly (see AAS section) are used, it is possible to introduce liquid samples directly to the atom cell. In circumstances such as these, it is necessary to use more robust air–acetylene or nitrous oxide–acetylene flame, or perhaps an ICP. The use of an ICP as an atom cell for AFS measurements has led to the development of a number of different techniques, for example, ASIA, an acronym for atomizer, source, ICPs in AFS. This technique uses a high-powered ICP as a source and a low-powered ICP for the atom cell. It has been found that ICP-AFS yields linear calibrations over 4–6 orders of magnitude and is more sensitive than inductively coupled plasma atomic emission spectroscopy (ICP-AES).

Several techniques have been developed that use an electrothermal atomizer as an atom cell. LIF has been discussed previously, but other techniques such as laser-excited atomic fluorescence spectroscopy (LEAFS) also exist, although are not used routinely.

Interferences

Atomic fluorescence has the advantage of being less prone to spectral interferences than either AES or AAS.

Molecular fluorescence is less of a problem than molecular absorption is in AAS. Scatter from the light source and quenching from the gaseous species in the atom cell are often the major sources of interference. For many applications where the analyte is separated from the matrix (e.g., vapor generation), chemical interferences may exist; for example, the presence of high concentrations of some transition metals may interfere in the hydride formation process. This will inevitably lead to errors in the measurement unless preventative steps are taken.

Detection Limits

A discussion of the detection limits for the different approaches utilizing atomic fluorescence is difficult because they depend so heavily on the type of source used. Similarly, samples introduced in the vapor phase tend to yield substantially improved limits of detection (LODs) when compared with those introduced as a liquid. In general, if an EDL is used as a source and a circular flame as an atom cell, LODs at the $\mu\text{g l}^{-1}$ level are obtainable. Improvement will be made if a laser is used as a source. If the sample is introduced as a vapor, LODs at the ng l^{-1} level are obtained. The use of an ICP as an atom cell leads to LODs at the $\mu\text{g l}^{-1}$ level if a normal HCL is used as the source, improving by approximately an order of magnitude if a BDHCL is used. If an electrothermal atomizer is used in conjunction with a laser, the best LODs of all are obtained.

Conclusions

AFS is a popular technique for those analytes that readily form vapors, and specialized instrumentation is now available for individual elements. Such instruments are simple to operate, are easily automated, and offer good sensitivity and freedom from interferences. The use of other flame-based fluorescence techniques has waned considerably over the years, but research continues into the use of electrothermal atomizers and ICPs as atom cells, reflecting the superior LODs that are potentially available. The availability of tunable lasers may also encourage the resurgence of AFS as a routine analytical tool.

Introduction

Forensic science continues to be a broad and growing area of research within the scientific community and a fascination to the general public. The term forensic stems from the Latin word *forensis*, which is translated as ‘public’ or ‘in the forum’ where debate is common. Today forensic debate is generally applied to legal arguments within the judicial system, where related scientific studies are termed forensic science and are practiced in support of investigatory and judicial processes.

The goal of forensic science is to identify facts related to evidentiary materials, which are inevitably left at a crime scene. What is the history of the sample? What is the source of the material? Is there an association between a known material and a questioned source or person of interest? With correct interpretation, these facts define truth and lead to just legal outcomes. Such facts are generated through forensic analyses that may include trace multielement and isotopic abundance determinations whose unique pattern results in a ‘fingerprint’ that can be used to define an association (‘match’) or discrimination (absence of a ‘match’).

Atomic spectroscopy and mass spectrometry are valuable techniques in forensic investigations primarily due to their high sensitivity for trace element and isotope detection. Additionally, the capability to analyze multiple elements within a sample, with good precision, provides

increased discrimination power and confidence in associating questioned materials to known sources. There are many other considerations in selecting an analytical approach for multielement or isotopic analysis. Precious samples are often very small, so nondestructive analysis techniques that do not alter or consume the evidence are favored. Techniques with very high precision and accuracy enable the analyst to detect subtle differences in samples that are otherwise indistinguishable.

Atomic spectroscopy and spectrometry techniques commonly used in forensic science include X-ray fluorescence (XRF), inductively coupled plasma atomic emission spectrometry (ICP-AES), and inductively coupled plasma mass spectrometry (ICP-MS). Emerging techniques include laser-induced breakdown spectroscopy (LIBS) and laser ablation ICP-MS (LA-ICP-MS) for elemental analysis, and high precision multi-collector ICP-MS (MC-ICP-MS) for inorganic isotope ratio mass spectrometry. Some of the more common methods are summarized in **Table 1** along with general analytical figures of merit. Each tends to have both advantages and disadvantages, but most have demonstrated the ability to be highly discriminating. In selecting a method, a forensic scientist will consider the sample size, homogeneity, matrix, and most importantly the elements or isotopes that have been previously determined through controlled studies to be discriminating. Other considerations include the required sensitivity (based on likely impurity levels), the degree of destructiveness, and the method precision, which contributes to the certainty of the ‘match.’

The most obvious distinctions in **Table 1** arise between optical spectroscopy and mass spectrometry and also between solids analyses (essentially nondestructive) and solution analyses. Optical spectroscopy is generally less sensitive than mass spectrometry, but can benefit from better precision and lower cost of implementation. Mass spectrometry can be prone to matrix effects because mass (not photons) is sampled into the instrument and detected directly. As a result, ion extraction can be affected by matrix elements and can lead to instrument drift and changes in relative ion transmission and detection efficiencies, although methods (elemental separations and internal standards) exist to correct for these effects. The benefit of mass spectrometry, however, is improved sensitivity for ultra-trace detection, which can provide alternate or additional elements for comparison, and the ability to detect individual isotopes.

Solids analyses such as LA-ICP-MS generally preserve the sample and tend to have higher throughput

Table 1 Comparison of several common forensic elemental and isotopic methods

Operating principle	Highly energetic X-rays knock out an inner shell electron. Relaxation of an outer shell electron into the vacant position causes emission of characteristic X-rays.	Laser photons induce matrix breakdown at sample surface. Characteristic emission lines are produced in the UV, VIS, and near IR range.	Dissolved samples are aspirated from a nebulizer and the aerosol is transported into the ICP. After desolvation, atoms are excited and emit photons at characteristic wavelengths.	Aspirated aqueous samples are transported to the ICP, desolvated, and ionized. Ions sampled from the plasma, focused into a mass filter, and detected based on mass-to-charge ratio.	Laser photons remove material from sample. Submicron-sized particles are transported into the ICP, which atomizes and ionizes the ablated material; ions are detected by MS.	Uses standard ICP aerosol introduction methods, but is dedicated to simultaneous detection of element isotopes for high precision isotope ratio analysis.	High energy primary ion beams sputter secondary ions from solid surfaces. Ions are extracted for mass analysis.	Elements are ionized on a high temperature filament and are extracted for a mass analysis.

than solution-based techniques in large part due to the sample preparation required for solution-based analyses. Benefits of solution-based techniques include more representative sampling of inhomogeneous materials, typically higher sensitivity, and improved quantification and quality control measures – calibration, calibration checks, matrix effect corrections, and so on. The forensic scientist will consider several such issues when selecting the appropriate test, or sequence of tests, to maximize the amount of useful forensic information for a given sample type.

Multielement and Isotopic Fingerprinting

The distinct pattern of a multielement optical or mass spectrum obtained from a material analysis is often referred to as a 'fingerprint,' having an obvious reference to the distinctiveness of a latent fingerprint found on an object and the ability to associate that print to an individual, and hence the individual to the object. It is both the suite of detectable elements and their intensities (related to concentration) that define the spectral fingerprint of a sample. The number of distinguishable combinations can be quite large based on the distribution of possible concentrations for each element, the number of non-correlated elements detected, and the precision of the measurements. Multielement and isotopic analyses have been applied to a broad range of sample types including glass, paint, bullet lead, soil, drugs, nuclear materials, and various metals. Several representative applications are presented here.

Glass Analysis

The forensic analysis of glass is a classic example of the utility of multielement fingerprinting for material associations. Glass is a commonly encountered material in crime scene investigations. Vehicular hit-and-run can result in headlamp or windshield fragments. Burglaries can result in shattered window panes that often backscatter onto the perpetrator's clothing or embed in the soles of shoes, later to be recovered from the suspect at another location. It is important to be able to associate or discriminate the recovered sample with that obtained from the crime scene. Historically, refractive index (RI), a nondestructive technique, served this purpose well. However, the ability to discriminate glass based on RI has diminished due to improvements in manufacturing capabilities. This has resulted in an industry-wide reduction in RI variability and a need for alternative measurement methods that would provide increased discrimination power.

Trace element analysis has proven to provide the needed specificity for forensic comparisons of glass. A number of elemental analysis methods have been tested

including energy and wavelength dispersive X-ray fluorescence (ED-XRF, WD-XRF), neutron activation, atomic absorption, and spark source mass spectrometry, but ICP-AES and ICP-MS tend to be the most commonly employed methods currently in use. **Table 2** shows a comparison of the relative discriminating power of RI, EDXRF, ICP-AES, and combinations of these methods. Pair-wise comparisons of 81 sheet glass samples (3240 possible comparisons) were made using each technique individually or a combination of techniques. ICP-AES analysis of nine elements (Al, Ba, Ca, Fe, Mg, Mn, Na, Sr, and Ti) provided 10 times the discriminating capability of RI and EDXRF combined.

In assessing the forensic utility of a technique, it is important to minimize quantitative errors and to understand all sources of variance that define the discriminating power. The discriminating power of a technique depends on the variance of a signature or group of signatures (e.g., multiple element concentrations) in the population, the variance of the signature(s) within the sample (homogeneity), and the variance of the analytical method. Ideally, one would have a small analytical bias and large total variability, with most of this variability arising from within the population and not within the method or the sample. Additionally, individual signatures should be tested and found to be non-correlated, providing independent and meaningful information. Empirical studies and statistical analysis of variance have identified Sr, Ti, Fe, Ba, Mn, Ca, Al, and Na as discriminating elements for glass when using ICP-AES and Zr, Hf, Sr, Y, Nd, Ce, and Ba as discriminating elements for ICP-MS.

Table 2 Frequency of indistinguishable pairs from 81 sheet glass samples (3240 comparisons)

<i>Comparison parameter and criteria</i>	<i>No. of indistinguishable pairs</i>	<i>Frequency</i>
(1) $n_D \pm 0.0002$	648	1:5.0
(2) $n_D \pm 0.0001$	418	1:7.8
(3) (1) and $n_C \pm 0.0004$ and $n_F \pm 0.0004$	487	1:6.7
(4) (2) and $n_C \pm 0.0002$ and $n_F \pm 0.0002$	178	1:18.2
(5) EDXRF	305	1:10.6
(6) (5) and (3)	81	1:40
(7) (5) and (4)	33	1:98
(8) ICP-AES	3	1:1080
(9) (8) and (3)	3	1:1080
(10) (8) and (4)	2	1:1620

Note: n_D , n_F , n_C , represent RI measurements at three different wavelengths.

Although providing the highest degree of accuracy and precision, solution-based methods such as ICP-AES are destructive techniques and require significant sample preparation time. Laser-based methods are of great forensic interest because of the low sample consumption (~ 300 ng, $50\ \mu\text{m}$ ablation spot), rapid analysis, and good discrimination power. An example of multielement fingerprinting of glass using LA-ICP-MS is shown in **Figure 1**, where five glasses of similar RI were measured on 10 different occasions over a two-month period. Ternary plots demonstrate the ability to discriminate each glass sample via LA-ICP-MS and the implicit utility of element ratios as a discrimination metric.

Another benefit of laser ablation is the ability to rapidly obtain depth-resolved multielement analysis.

Although still in the development stage, this technique has been demonstrated for the analysis of automotive paint, which is applied in multiple layers. The results shown in **Figure 2** show that elemental composition can be obtained for specific layers of the automotive paint coating and that discrimination is adequate for the comparison of samples of different origins. Depth information is yet another characteristic feature for comparison, with matches at each layer providing further confidence in associations.

LIBS is an emerging technique for the analysis of glass. It involves optical detection of characteristic element emissions from a laser plume. This new approach demonstrates comparable discrimination as compared to LA-ICP-MS and μXRF and may provide a high-throughput, low-cost alternative for multielement compositional fingerprinting.

Bullet Lead Analysis

The compositional analysis of bullet lead is another area of forensic science in which atomic spectroscopy has played a central role and provides an interesting case study. When a gun is discharged, it leaves distinctive marks that are unique to the weapon and allow a match of striation marks. Often however, the firearm cannot be located, or the bullet fragment is so disfigured that such comparisons are not possible. A comparison of multielement compositions allows for associations between recovered bullet fragments and recovered ammunitions to be made.

Both trace element and isotope ratio analysis of bullet lead can be used in a complementary manner. The results of one set of isotope ratio analyses are shown in **Figure 3**. In this case, one of two restaurant robbers was responsible for the death of two persons. The question of who fired the lethal shots was disputed. Antimony/lead ratio analysis suggested that bullet 3, associated with assailant 1, was indistinguishable from particles recovered from the victims. Isotope ratio data obtained from a magnetic sector field ICP-MS (**Figure 3**) confirmed this association. The lead three-isotope plot shows no statistical difference between the recovered particles and bullet 3. Conversely, Sb/Pb ratios and Pb isotopic results clearly indicate that assailant 2's ammunition (bullets 1 and 2) was not consistent with the hypothesis that he/she fired the lethal shots.

The United States' Federal Bureau of Investigation adopted ICP-AES as its preferred method of bullet lead analysis due to its multielement capability and its demonstrated accuracy and precision for elements with a significantly broad range of compositions. Currently, Sb, Sn, Cd, As, Cu, Bi, and Ag are measured and provide high discrimination capability. Using these seven elements, ICP-AES analysis has been shown to be highly discriminating for lead projectiles. In general, less than 0.1% of samples of different origins were found to be indistinguishable.

Figure 2 Element-ratio plots for the individual layers of automotive paint demonstrate the multielement discrimination that is possible as a function of depth ($\sim 100\ \mu\text{m}$ total depth of analysis crater). Reproduced with permission from Hobbs AL and Almirall JR (2003) Trace elemental analysis of automotive paints by laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS). *Analytical and Bioanalytical Chemistry* 376: 1265–1271, Springer Science + Business Media.

Figure 3 Lead isotope ratios from lead particles obtained from the victim's bodies are shown to be indistinguishable from bullets from assailant 1 (Projectile 3), both of which are statistically distinct from assailant 2 bullets (Projectiles 1 and 2). Reproduced with permission from Ulrich A, Moor C, Vonmont H, Jordi HR, and Lory M (2004) ICP-MS trace-element analysis as a forensic tool. *Analytical and Bioanalytical Chemistry* 378: 1059–1068, Springer Science + Business Media.

In 2003, the National Research Council was invited to conduct a review of the FBI's analytical methodology, data reduction methods, statistical analysis, and interpretations. The results of this review were published in a report, *Forensic Analysis: Weighing Bullet Lead Evidence*. A full discussion of the findings is beyond the scope here, but the report is a highly recommended reference as it not only provides background for the role of atomic spectroscopy for compositional analysis but also provides critical insight on the accurate data interpretation and use of bullet lead compositional analyses. In brief, great emphasis is often placed on compositional variations between two samples (such as two bullets from one box) relative to method variations. However, the report emphasized that results have to be interpreted in the context of manufacturing processes, where thousands to millions of bullets can originate from the same compositionally indistinguishable volume of lead (a melt), and that ammunition distribution uncertainties further complicate the interpretation of results.

Isotope ratio analysis is a mass spectrometry-based technique that holds some promise for forensic applications, particularly for bullet lead. The isotopic abundances of radiogenic isotopes such as Pb, for example, can vary widely and are dependent on the age of the lead ore. The modern isotopic composition of Pb results from the radioactive decay of uranium and thorium as follows:

As a result, isotope ratios in bullet lead can be strongly discriminating due to variability in regional ore sources. Current mass spectrometric measurement precision is able to discern these differences and provides data complementary to elemental analysis.

Thermal ionization mass spectrometry (TIMS) is the traditional approach to precise isotope ratio analysis, but recent advances have made ICP-MS the choice for lead isotopic analysis. Unlike TIMS, ICP-MS does not require complete chemical separation, greatly simplifying the laboratory procedure. Additionally, the advent of simultaneous MC-ICP-MS allows high precision measurements (~100 ppm), although the instrument cost will likely limit its widespread implementation in local forensic labs.

Nuclear Materials Analyses

The role of multielement compositional and isotopic abundance analyses is arguably more central to nuclear forensic analysis than in criminal forensic investigations. Nuclear forensics investigations generally involve the

characterization of nuclear materials that are interdicted during a smuggling attempt or collected after the detonation of a radiological dispersion device or a nuclear weapon.

The principal goal of a nuclear forensic investigation is the determination of material origin. The answers to several questions can lead to successful attribution of the event to the perpetrators. What was the nuclear material – uranium, plutonium, or other radioisotopes? What is the isotopic composition – low isotopic enrichment for use as nuclear fuel or highly enriched for weapons applications? Where was the mineral ore mined? Under what reactor conditions was Pu produced? How was it chemically processed or how were its isotopes enriched? When was it made, or more accurately, when was it last purified? When was control of the nuclear material lost and what was its distribution pathway? In the case of a nuclear detonation, nuclear debris and fallout is measured to determine the original composition of the nuclear material and the device design. In these cases, the ability to quantify bulk and trace elemental constituents and isotopic abundances allows many of these questions to be answered, especially in combination with international nuclear materials databases and computational modeling.

Traditional criminal forensic material examinations – fibers, dust, pollen, and soil for example – remain an important component of nuclear forensic investigations. This is particularly true as related to route attribution, where regionally specific trace evidence can provide indications of the smuggling route. Physical characterization including macroscopic and microscopic material features (size, shape, surface roughness, and morphology) can provide information related to its intended use, processing, and origin. Radiological (alpha, beta, and gamma) measurements depend on the energy-specific radiation emitted from a radionuclide to provide a rapid hazard analysis and radionuclide identification. Chemical analysis, including gas chromatographic separations with mass spectrometric analysis, can provide organic signatures (e.g., kerosene oils and tributyl phosphate) that indicate a specific reprocessing operation.

Yet it is the accurate and precise determination of multielement concentrations and isotopic analysis that provide the majority of information regarding nuclear material origins, processing history, and post-detonation material characterization. In the case of uranium, the isotopic composition and elemental impurities can be indicative of the original ore material source and subsequent purification and enrichment processes, suggesting its intended use. For Pu, the isotopic composition is dependent on the isotopic composition of the irradiated uranium fuel and the neutron exposure characteristics. Minor isotopes (^{232}U , ^{236}U) are indicators that reprocessed material is involved, and the in-growth of daughter isotopes from uranium (e.g., ^{232}Th) and plutonium (e.g., ^{241}Am) provides

a chronometer that can be used to determine the date since processing.

Elemental analysis is most often performed with XRF, ICP-AES, or ICP-MS. Secondary ion mass spectrometry (SIMS) is particularly useful in the isotopic and elemental analysis of small samples or for the spatially resolved characterization of individual particles or inhomogeneous mixtures.

TIMS remains the isotopic analysis technique of choice for nuclear materials analysis, particularly for small samples (sub-picogram to nanogram) of uranium and plutonium which are loaded either as a solution residue, or on a resin bead, that is vaporized and ionized at a heated filament surface from which the ions are extracted and analyzed. Quantitative analysis is possible with the addition of a known quantity of an isotopic spike of known enrichment. Measurement of the spiked and unspiked sample allows calculation of the material mass via the isotope dilution equation. Thus, TIMS provides both high precision and accuracy for ultra-trace elemental and isotopic analysis. However, TIMS requires complete elemental separation before analysis. Without element purification, ionization inefficiencies, arising from the presence of easily ionized elements, and associated chemical and isobaric interferences degrade TIMS performance. This sample processing is arduous and adds greatly to sample reporting times.

Inductively coupled plasma mass spectrometry is becoming more common in nuclear materials analysis. High sample throughput and continual improvement in small sample analysis capabilities are the primary reason for the increasing use. Additionally, the ability to couple alternative sampling and elemental separation techniques on-line with ICP-MS (such as laser ablation sampling of solids and on-line separation devices) provides flexibility and efficiency with regard to sample types and sample throughput.

Multi-collector analysis is a common approach for high precision analysis via TIMS. In this approach, ions are dispersed according to mass (more accurately, mass to charge ratio) upon exiting a magnetic field and are detected on an array of detectors. All isotopes are detected simultaneously, overcoming measurement uncertainties arising from beam instabilities. Such approaches are critical when high precision isotope ratio measurements are required. For example, uncertainties in decay-product ratios translate into uncertainty in assigning a material age. Additionally, signatures available from subtle natural variations in radiogenic isotope abundances (e.g., lead isotope ratios) require high precision analyses. More recently, multi-detector arrays have been interfaced with ICP-MS and SIMS, combining the benefits of simultaneous detection with the benefits of both sampling and ionization techniques.

Conclusion

While evidence may only be present at microscopic sizes or ultra-trace quantities, no physical criminal act is committed without a trace. It is the challenge of forensic scientists to locate increasingly small samples, characterize, analyze, and correctly interpret results within the context of statistical uncertainty. The certainty of a 'match' must be assessed in the context of variability within the whole population, which more often than not cannot be completely assessed. Nevertheless, atomic spectroscopy and mass spectrometry will continue to be important techniques in the hands of trained forensic scientists who understand the full context of sampling, analyses, and statistical data reduction and interpretation of evidentiary materials. The ability to measure multiple elements and isotopes at trace and ultra-trace levels lends itself to increasingly smaller samples and improved measurement precision and solidifies the future of atomic spectroscopy and mass spectrometry in forensic science.

Atomic Spectroscopy, Historical Perspective

CL Chakrabarti, Carleton University, Ottawa, Ontario, Canada

© 1999 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, volume 1, pp 56–58, © 1999, Elsevier Ltd.

Professor BV L'vov, the inventor of the very powerful analytical technique known as graphite furnace atomic absorption spectroscopy (GFAAS), has rightly pointed out in the introduction of his definitive book entitled *Atomic Absorption Spectrochemical Analysis* that 'The discovery of atomic absorption and the history of research into it are integral parts of the entire history of spectroscopy and spectrochemical analysis'. Indeed, the early history of atomic spectroscopy, as far as spectrochemical analysis was concerned, consisted of the development of emission spectrochemical analysis, which was usually dependent on Fraunhofer lines (atomic absorption lines) for wavelength calibration.

Following Newton's study of the spectrum of the Sun in 1666, there was a period of almost 136 years entirely concerned with emission spectroscopy. Only in 1802 did Wollaston report the presence of dark bands in the continuum emission spectrum of the Sun and, after a more detailed study by Fraunhofer (1814), Brewster (1820) was able to ascribe them to absorption of radiation within the Sun's atmosphere. Another 40 years passed before Kirchhoff and Bunsen showed that one of these dark bands in the emission spectrum of the Sun corresponded exactly to the yellow emission band obtained when sodium vapour is heated in a flame. This led Kirchhoff to deduce that the Fraunhofer lines in the solar spectrum are absorption lines of elements whose flame emission spectra would contain lines at exactly the same position in the spectrum. Their work enabled Kirchhoff to develop the fundamental relationship between emission and absorption spectra: any species that can be excited to emit radiation at a particular wavelength will also absorb radiation at that wavelength. Thus, Kirchhoff not only laid the foundations of atomic absorption methods of chemical analysis but also gave a striking example of their power. Indeed, it is difficult to imagine a more convincing and dramatic demonstration. Bunsen and Kirchhoff are thus rightfully considered to be founders of spectrochemical analysis. However, it is surprising that almost a century after the work of Bunsen and Kirchhoff, the potentialities of atomic absorption measurements remained unexplored and unsuspected. Why?

As Alan Walsh has presented in his perceptive analysis of the reasons, it seems likely that one reason for neglecting atomic absorption methods was that Bunsen and

Kirchhoff's work was restricted to visual observation of the spectra. In such visual methods, the sensitivity of emission methods was probably better than that of absorption. Not only was the photographic recording of the spectra more tedious but also the theory seemed to indicate they would only prove useful for quantitative analysis if observed under very high resolution. But possibly a more fundamental reason for neglecting atomic absorption is related to Kirchhoff's law (1859), which states that the ratio of the emissive power E and the absorptive power A of a body depends only on the temperature of the body and not on its nature. Otherwise radiative equilibrium could not exist within a cavity containing substances of different kinds. The law is usually expressed as

$$\frac{E}{A} = K(\lambda T)$$

where $K(\lambda T)$ is a function of wavelength and temperature.

This law is perfectly correct but unfortunately much and possibly most of the subsequent teaching concerning it has been misleading. In most textbooks and lessons on this subject the enunciation of the law is followed by a statement to the effect that 'this means good radiators are good absorbers, poor radiators are poor absorbers'. This statement is patently absurd without any reference to temperature or wavelength.

This erroneous conclusion has been made, presumably, because Kirchhoff's constant, K , as he so clearly pointed out, is a function of wavelength and temperature. He was unable to find an analytical expression for it, and it was not deduced until 1900 by Kirchhoff's successor Max Planck, at the University of Berlin, as Planck's distribution function. Many spectroscopists were misled by the widely held but misleading assumptions regarding the implications of Kirchhoff's law. What is even more surprising is that numerous spectroscopists wrote papers on atomic emission methods and referred to the problems caused by the effects of self-absorption and self-reversal, and yet failed to make the small-step connection between atomic emission and atomic absorption. It was left to Alan Walsh, whose research experience in atomic emission spectroscopy and molecular absorption spectroscopy virtually compelled him to see the obvious connection. Walsh expressed this experience in his

inimitable way in the following words: 'It appears to be true that "having an idea" is not necessarily the result of some mental leap: it is often the result of merely being able, for one sublime moment, to avoid being stupid!'

Walsh in 1953 and Alkemade and Milatz in 1955 independently published papers indicating the substantial advantage of atomic absorption methods over emission methods for quantitative spectrochemical analysis. Alkemade and Milatz considered only the selectivity in atomic absorption methods, but Walsh discussed general problems of development of absolute methods of analysis. During his early experiments with flame atomizer burners, Walsh encountered the problems which arise when measuring atomic absorption using a continuum source problems, which might have been responsible for the neglect of atomic absorption methods. The use of a sharp-line source such as a hollow-cathode lamp not only solved this problem, it also provided the atomic absorption method with one of its important advantages, that is, the ease and certainty with which one can isolate the analysis line. The concept of 'putting the resolution in the source' also permitted the use of a simple monochromator since the function of the monochromator, in such a case, is only to isolate the analysis line from the neighbouring lines and the background.

GFAAS has been widely used as a spectrochemical trace-analytical technique during the last 40 years. L'vov pioneered most of the theoretical and experimental developments in GFAAS and provided a masterly treatment of the possibilities of GFAAS in a paper entitled 'Electrothermal atomization—the way towards absolute methods of atomic absorption analysis'. RE Sturgeon, who has been responsible for much of the development of GFAAS, presented a critical analysis of what it does and what it cannot do. AKh Gilmutdinov, who did much of the theoretical development of GFAAS in the 1990s, also elucidated the complex processes and reactions that occur in an electrothermal atomizer by digital imaging of atomization processes using a charge-coupled device camera in the author's research laboratories.

Atomic spectroscopy in the three variations that are most commonly used in spectrochemical analysis, atomic absorption, atomic emission and atomic fluorescence, are all mature techniques, with their particular areas of strengths and weaknesses now well recognized. Many a battle has been fought and won to establish the superiority of one or the other technique over the rival techniques. It is sometimes claimed that inductively coupled plasma mass spectrometry (ICP-MS), which has the winning combination of high-temperature ionization of elements in a plasma, with the detection of the ions by mass spectrometry, is the ultimate trace-analytical technique that will triumph over the rival techniques. However, such claims are based on the limited applications of these techniques by practitioners whose allegiance to their own techniques gives more credit to their loyalty than to their

scientific objectivity, as elaborated in the following paragraph. Some have also predicted the imminent demise of GFAAS as a trace-analytical technique. Such a prediction, based as it is on inadequate comprehension of the enormous complexities and extreme diversities of real-life situations requiring a variety of trace-analytical techniques which possess, some special capabilities not possessed by many analytical techniques, is destined to be false, as is shown in the following text.

In the author's research laboratories in recent years, PhD students and adjunct research professors have been doing research on the chemical speciation of potentially toxic elements in the aquatic, the atmospheric and the terrestrial environment. Because freshwaters and soils are systems that are usually far removed from equilibrium, our research is mostly directed to the development of kinetic schemes of chemical speciation which require routine use of ICP-MS and GFAAS to measure the kinetics of metal uptake from aqueous environmental samples. As such, hundreds of determinations of trace and ultratrace elements are routinely made every week. For these determinations, the latest models of two ICP-MS and several GFAAS systems exist. The performance characteristics of ICP-MS and GFAAS for kinetic studies of real-life, aqueous environmental samples have been analyzed for a period covering 6 years from 1993 to 1998, and the following inescapable conclusions are derived. The analytical sensitivities of both ICP-MS and GFAAS for toxic metals are comparable. For kinetic runs on aqueous environmental samples, ICP-MS has the great advantage of providing continuous sampling with numerous data points having adequate time resolution, whereas GFAAS provides discrete sampling with fewer data points having inadequate time resolution. However, in the most important and decisive criterion of sample compatibility with the technique, ICP-MS fails completely on account of its inability to handle any solutions containing significant amounts of solute materials or corrosive chemicals such as hydrofluoric acid and strong inorganic acids and bases, whereas GFAAS can readily handle such samples. Since the aqueous environmental samples for kinetic runs are always pre-treated with solutes in the form of acid-base buffers and since such solutions cannot be diluted to make them acceptable to ICP-MS, it is not possible to use ICP-MS for such kinetic studies without fouling the interior of the ICP-MS equipment with encrustations of the solute materials, which do serious damage. The alternative then is GFAAS, in spite of all its limitations. Because of the easy compatibility of GFAAS with the difficult sample type described earlier, GFAAS will continue to be used, as it is used now, until another new analytical technique, having all the advantages of ICP-MS without its fatal deficiencies mentioned earlier, is invented, developed and tested using real-life samples, that is for a long time.

Symbols

A	absorbance (decadic)
d	sample thickness
d_e	<i>effective thickness</i> (Harrick)
d_p	penetration depth
$\bar{d}$	mean penetrated layer thickness
E	electric field
E_x	electric field component in x-direction
E_y	electric field component in y-direction
E_z	electric field component in z-direction
$\bar{J}$	energy flux (time average)
m_x	x-component of the unit vector in the direction of <i>M</i>
m_y	y-component of the unit vector in the direction of <i>M</i>
m_z	z-component of the unit vector in the direction of <i>M</i>
M	transition dipole moment
n	refractive index
$\hat{n}$	complex refractive index
N	number of active internal reflections
r	ratio of reflected to incident field
R^{ATR}	dichroic ratio related to ATR spectra
R	dichroic ratio
R	reflectance
S_γ = S_{mol}	molecular order parameter
S_δ	tilt order parameter
S_θ	order parameter with respect to the molecular axis
S_{seg}	segmental order parameter
S	Poynting vector (time average)
t	ratio of transmitted to incident field
T	transmittance
z	distance from surface
 , ⊥	parallel- and perpendicular- polarized light, respectively
*	conjugate complex
α	absorption coefficient
α	angle between transition dipole moment and z-axis
δ	phase shift
ε	permittivity
ε	molar absorption coefficient
ε₀	permittivity of vacuum

ε_r	relative permittivity (dielectric constant)
η	amplitude
θ_c	critical angle
θ_i	angle of incidence
θ_r	angle of reflection
θ_t	angle of refraction (transmission)
κ	absorption index
λ	wavelength
μ	permeability
μ₀	permeability of vacuum
μ_r	relative permeability
ν	number of equal functional groups per molecule
$\tilde{\nu}$	wavenumber
ρ	reflectance
τ	transmittance
τ	relaxation time
Γ	surface concentration
φ	phase lag
ω	angular frequency

Introduction

Chemical reactions that occur at gas–solid and liquid–solid interfaces are of central importance to a variety of research and technological areas, including biomembranes, drug design, drug–membrane interaction, biosensors, chemical sensors, heterogeneous catalysis, thin film growth, semiconductor processing, corrosion and lubrication. Many methods are used for interface studies, ranging from most simple ones like the octanol–water two-phase system for mimicking the partition of a drug between a biomembrane and the surrounding water, to most specialized and expensive techniques such as low-energy electron diffraction (LEED), Auger electron spectroscopy (AES), X-ray photoelectron spectroscopy (XPS/ESCA) and ion scattering spectroscopy (ISS).

Among this palette of techniques, optical reflection spectroscopy in the mid- and near-IR range occupies an important complementary position. The basic equipment consists of a commercial IR spectrometer and a suitable reflection accessory that usually fits into the sample compartment of the spectrometer. Many reflection techniques permit *in situ* applications, and if applied in

¹In Memory of N Jim Harrick.

the mid-IR, result in quantitative and structural information on a molecular level. Moreover, IR reflection spectroscopy features a very high performance-to-price ratio.

There is a wide range of different spectroscopic reflection techniques. First one should distinguish between internal (total) and external reflections. Attenuated total reflection (ATR) belongs to the first group. It makes use of the evanescent wave existing at the interface of the IR waveguide and the sample. Commercial ATR attachments differ mainly in shape and mounting of the internal reflection element (IRE) in the light path. Most IREs enable multiple internal reflections, a prerequisite for monolayer and sub-monolayer spectroscopy, and referred to as MIRE.

A variety of external reflection techniques are in use. In specular reflection (SR), the radiation reflected from the front surface of a bulk sample is collected. SR is often measured at or near-normal incidence. Reflected spectral energy depends on the absorption behaviour of the sample. In regions of strong absorption, the reflected energy is enhanced with respect to nonabsorbing spectral regions; moreover, the reflection spectrum is usually very different from a corresponding absorption (AB) spectrum obtained by a transmission experiment. AB spectra may, however, be calculated from SR spectra by means of the Kramers–Kronig transformation (KKT). Corresponding software for SR data processing is supplied with most commercial IR instruments. While specular reflectance is measured at or near-normal incidence, IR reflection–absorption spectroscopy (IRRAS) works from approximately 10° to grazing incidence. In this case the sample is placed on a reflecting substrate, usually a metal. The portion of reflected light from the sample surface is generally small compared with the energy reflected off the metal surface. Therefore, IRRAS data and transmission (T) data are analogous. From Fresnel's equations (see later), it follows that parallel ($\parallel$) and perpendicular ($\perp$) polarized electromagnetic waves undergo different phase shifts upon reflection. This phase shift is 180° for $\perp$ -polarized light at nonabsorbing interfaces. As a consequence, incoming and reflected beams cancel at the interface (node). However, at large angles of incidence $\parallel$ -polarized incident light results in an enhanced electric field component perpendicular to the reflecting interface (z -axis). For thin samples, that is sample thickness (d) much smaller than the quarter wavelength ($\lambda/4$) of the reflected light, RA spectra report only partial information on orientation. It should be noted, however, that for a complete orientation analysis spectra obtained with light polarized in the plane of the interface (x, y -plane) is also necessary. ATR fulfils this requirement, in contrast to RA.

Diffuse reflectance (DR) is successfully applied to obtain IR spectra of rough (scattering) or dull surfaces, that is of media intractable by other reflection techniques.

The interpretation of DR spectra, however, is sometimes handicapped by the fact that they may be a mixture of AB and SR spectra. DR spectroscopy is a sensitive tool, especially when used with an IR Fourier transform (FT) spectrometer (DRIFT).

Elucidation of structure–activity relationships is the aim of many applications of reflection spectroscopy to thin layers at interfaces. In this context, polarization measurements are of considerable importance, since molecules at interfaces exhibit often induced ordering.

Low signal intensities are common in different kinds of interface spectroscopy, especially when the sample consists of a monolayer or even submonolayer as usual in heterogeneous catalysis and substrate–biomembrane interaction. Although modern FTIR spectrometers exhibit very high stability, signal-to-noise (S/N) ratio enhancement by data accumulation is limited by environmental and instrumental instabilities. The fact that most commercial FT instruments are operated in a single-beam (SB) mode is disadvantageous in this respect, because the longer an experiment lasts, the greater is the time lag between sample and reference data, which facilitates the intrusion of instabilities. Several optional extras are available to reduce the time lag between acquisition of sample and reference spectra.

One possibility is the conversion of the single-beam instrument into a pseudo-double-beam instrument by means of a shuttle which moves alternately the sample and reference into the IR beam. Such attachments were first developed for transmission experiments and were later adapted for ATR measurements. In the latter case, the sample and the reference are placed on top of one another on the same trapezoidal MIRE. A parallel beam of half the height of the MIRE is directed alternately through the upper and lower half of the MIRE by computer-controlled vertical displacement of the ATR cuvette. This method is referred to as single-beam sample reference (SBSR) technique and is described in more detail later.

Polarization modulation (PM) in combination with IRRAS is a further possibility to enhance instrumental stability and background compensation when working at grazing incidence to a thin sample on a metal substrate. PM at approximately 50 kHz is achieved by means of a photoelastic modulator (PEM). Since under these experimental conditions the sample will only absorb light in the $\parallel$ -polarized half-wave, the $\perp$ -polarized half-wave of the signal is representative of the background, that is of the reference. Subtraction is performed by the lock-in technique within each PM cycle, that is 50 000 times per second. As a consequence, environmental and instrumental contributions are largely compensated.

Finally, it should be noted that a more general application of modulation spectroscopy can be used to obtain selective information on an excitable sample.

Modulated excitation (ME) spectroscopy can always be applied with samples allowing periodic stimulation via a periodic variation of any external thermodynamic parameter, for example temperature, pressure, concentration, electric field, and light flux. ME causes a periodic variation of the absorbance at those wavelengths that are typical for the molecules involved in the stimulated process. Phase-sensitive detection (PSD) by the digital lock-in technique adapted for FTIR instruments permits spectral registration of the modulated, that is affected, part of the sample. A typical feature of ME with PSD is the comparison of sample and reference within each period of stimulation. Within this time interval environmental and instrumental parameters are usually stable so that a very good baseline is achieved. Moreover, if one or more relaxation times τ_i of the kinetic response of the stimulated sample fulfil the condition $0.1 < \omega\tau_i < 10$, where ω denotes the angular frequency of stimulation, significant phase lags ϕ_i between stimulation and sample responses will occur which are related to the reaction scheme and the rate constants of the stimulated process.

Theory of Reflectance Spectroscopy

For a comprehensive description of the theory of reflectance, the reader is referred to the Further Reading section. In this article, theory will only be presented when necessary for a general understanding.

Fresnel's Equations

The theory of reflection and transmission of an electromagnetic wave by a plane boundary was first derived by Fresnel. The geometry of SR and transmission is depicted in **Figure 1**. The incident (i) plane wave consists of the parallel ($\parallel$) and perpendicular polarized ($\perp$) electric field components $E_{i\parallel}$ and $E_{i\perp}$, respectively. The corresponding components of the reflected (r) and refracted (transmitted t) field components are denoted by $E_{r\parallel}$, $E_{r\perp}$, $E_{t\parallel}$ and $E_{t\perp}$. Fresnel's equations relate the reflected and transmitted components to the corresponding incident components.

For a non-absorbing medium, that is for the absorption indices κ_1 and κ_2 equal to zero, one obtains for the ratio r between reflected and incident electric field

$$\begin{aligned} r_{\parallel} &= \frac{E_{r\parallel}}{E_{i\parallel}} = \frac{n_2 \cos \theta_i - n_1 \cos \theta_t}{n_2 \cos \theta_i + n_1 \cos \theta_t} \\ r_{\perp} &= \frac{E_{r\perp}}{E_{i\perp}} = \frac{n_1 \cos \theta_i - n_2 \cos \theta_t}{n_1 \cos \theta_i + n_2 \cos \theta_t} \end{aligned} \quad [1]$$

where $\parallel$ and $\perp$ denote parallel and perpendicular polarization, according to **Figure 1**. Eqn [1] may be

Figure 1 Specular reflection and transmission. The angles of incidence (i), reflection (r) and refraction (t) are denoted by θ_i , θ_r and θ_t , respectively. The corresponding electric field components are denoted by E . They are split into orthogonal portions, one parallel to the plane of incidence (x , z -plane) and the other perpendicular to this plane (parallel to y -axis). Accordingly, electric fields are referred to as parallel ($\parallel$) and perpendicular ($\perp$) polarized; n_1 , n_2 , κ_1 and κ_2 denote the refractive and absorption indices in the two media.

modified by introducing Snell's law of refraction:

$$n_1 \sin \theta_i = n_2 \sin \theta_t \quad [2]$$

resulting in

$$\begin{aligned} r_{\parallel} &= \frac{E_{r\parallel}}{E_{i\parallel}} = \frac{\tan(\theta_i - \theta_t)}{\tan(\theta_i + \theta_t)} \\ r_{\perp} &= \frac{E_{r\perp}}{E_{i\perp}} = -\frac{\sin(\theta_i - \theta_t)}{\sin(\theta_i + \theta_t)} \end{aligned} \quad [3]$$

As concluded from eqn [3], perpendicular polarized incident light undergoes a phase shift of 180° upon reflection, that there is a node at the reflecting interface resulting in zero electric field strength at this point. However, parallel polarized components remain in-phase. However, this conclusion holds no longer in the case of absorbing media.

The corresponding equations for the ratio t between transmitted and incident electric fields are

$$\begin{aligned} t_{\parallel} &= \frac{E_{t\parallel}}{E_{i\parallel}} = \frac{2n_1 \cos \theta_i}{n_2 \cos \theta_i + n_1 \cos \theta_t} \\ t_{\perp} &= \frac{E_{t\perp}}{E_{i\perp}} = \frac{2n_1 \cos \theta_i}{n_1 \cos \theta_i + n_2 \cos \theta_t} \end{aligned} \quad [4]$$

To modify eqns [1], [3] and [4] for absorbing media one has to introduce the complex refractive index. For an incoming plane-wave it is given by:

$$\hat{n} = n + i\kappa \quad [5]$$

where n is the refractive index and κ is the absorption index. As a consequence, r and t become complex and the resulting phase shifts differ from 0° and 180° as mentioned.

Energy Flux Density

The flux density of an electromagnetic wave is described by the Poynting vector. For the case of the plane-wave field, one obtains for the time average in the direction of propagation:

$$\bar{S} = \frac{1}{2} \sqrt{\varepsilon/\mu} E_0^2 \quad [6]$$

where μ is the permeability, that is the product of the permeability of vacuum μ_0 and the relative permeability μ_r which is unity for non-conductive materials, and ε denotes the permittivity which is the product of the permittivity of vacuum ε_0 and the relative permittivity (dielectric constant) ε_r which is complex for absorbing media, according to

$$\begin{aligned} \hat{\varepsilon}_r &= \hat{n}^2 = n^2 - \kappa^2 + i \cdot 2n\kappa \\ &= (n^2 + \kappa^2) \cdot \exp \left[i \cdot \operatorname{atan} \left(\frac{2n\kappa}{n^2 - \kappa^2} \right) \right] \\ &= |\hat{\varepsilon}_r| \cdot \exp(i \cdot \varphi) \end{aligned} \quad [7]$$

Introducing the absolute value of eqn [7] into eqn [6] results in, for non-conducting media,

$$\bar{S} = \frac{1}{2} \sqrt{\varepsilon_0/\mu_0} \sqrt{n^2 + \kappa^2} E_0^2 \quad [8]$$

Reflectance ρ and transmittance τ are defined as the ratios of the corresponding energy fluxes $\bar{J}$. According to eqn [8] they are proportional to the square of the electric field, that is

$$\rho = \frac{\bar{J}_r}{\bar{J}_i} = rr^* \quad \text{and} \quad \tau = \frac{\bar{J}_t}{\bar{J}_i} = \frac{\sqrt{(n_2^2 + \kappa_2^2)}}{\sqrt{(n_1^2 + \kappa_1^2)}} \frac{\cos \theta_t}{\cos \theta_i} tt^* \quad [9]$$

The factor $\sqrt{(n_2^2 + \kappa_2^2)}/\sqrt{(n_1^2 + \kappa_1^2)}$, which reduces to n_{21} for non-absorbing media, results from the change of dielectric (see eqn [8]), and $\cos \theta_t/\cos \theta_i$ takes account of the different cross-sections of the beam in media 1 and 2, respectively.

rr^* and tt^* , become r^2 and t^2 for non-absorbing media. In this case, eqns [1], [2] and [8] result in

$$\begin{aligned} \rho_{||} &= \left(\frac{n_{21}^2 \cos \theta_i - \sqrt{n_{21}^2 - \sin^2 \theta_i}}{n_{21}^2 \cos \theta_i + \sqrt{n_{21}^2 - \sin^2 \theta_i}} \right)^2 \\ \rho_{\perp} &= \left(\frac{\cos \theta_i - \sqrt{n_{21}^2 - \sin^2 \theta_i}}{\cos \theta_i + \sqrt{n_{21}^2 - \sin^2 \theta_i}} \right)^2 \end{aligned} \quad [10]$$

where n_{21} denotes the ratio of refractive indices of media 2 and 1, respectively (see **Figure 1**). For normal incidence, that is $\theta_i = 0$, eqn [10] reduces to

$$\rho_{||} = \rho_{\perp} = \left(\frac{n_2 - n_1}{n_2 + n_1} \right)^2 \quad [11]$$

To obtain the reflectance of an absorbing medium one may introduce eqn [5] into eqn [10] or [11]. The result for normal incidence is

$$\rho_{||} = \rho_{\perp} = \frac{(n_2 - n_1)^2 + (\kappa_2 - \kappa_1)^2}{(n_2 + n_1)^2 + (\kappa_2 + \kappa_1)^2} \quad [12]$$

It should be noted that in many applications medium 1 is air or a non-absorbing crystal, that is $\kappa_1 = 0$. It follows from eqn [12] that the reflectance increases with increasing absorption index of medium 2 (κ_2). In the limiting case of $\kappa_2 \rightarrow \infty$ one obtains $\rho \rightarrow 1$, that is a perfect mirror. Expressions for the more complicated case of oblique incidence to absorbing media have been derived (see Further Reading section).

The Kramers–Kronig Relations

For normal incidence ($\theta_i = 0$) and non-absorbing medium 1 ($\kappa_1 = 0$, see **Figure 1**), one obtains from eqns [1] and [5] the following expression for the complex ratio $\hat{r}(\theta_i = 0)$ between reflected and incident electric fields:

$$\begin{aligned} \hat{r}_{||}(\theta_i = 0) &= \frac{E_{r||}}{E_{i||}} = \frac{n_2 - n_1 + i\kappa_2}{n_2 + n_1 + i\kappa_2} = \eta \exp(i\phi) \\ \hat{r}_{\perp}(\theta_i = 0) &= \frac{E_{r\perp}}{E_{i\perp}} = \frac{n_2 - n_1 + i\kappa_2}{n_2 + n_1 + i\kappa_2} = \eta \exp[i(\phi + \pi)] \end{aligned} \quad [13]$$

where η and ϕ are the amplitude and phase of $\hat{r}(\theta_i = 0)$. They are functions of the wavenumber $\tilde{\nu}$ and related to each other by the Kramers–Kronig equations:

$$\begin{aligned} \ln \eta(\tilde{\nu}) &= \frac{2}{\pi} \int_0^\infty \frac{v \phi(v)}{v^2 - \tilde{\nu}^2} dv \\ \phi(\tilde{\nu}) &= \frac{2\tilde{\nu}}{\pi} \int_0^\infty \frac{\ln \eta(v)}{v^2 - \tilde{\nu}^2} dv \end{aligned} \quad [14]$$

Experimentally, $\eta(\tilde{\nu})$ can be determined, since it is related to the reflectance at normal incidence by

$\rho(\theta_i = 0) = \eta(\tilde{\nu})\eta(\tilde{\nu})^*$, that is $\eta(\tilde{\nu}) = \sqrt{\rho(\theta_i = 0)}$; see eqn [12]. The Drude model may be used to extrapolate the measurement to $\tilde{\nu} = 0$ and $\tilde{\nu} = \infty$. From $\eta(\tilde{\nu})$ and $\phi(\tilde{\nu})$ the components of the refractive index can be calculated according to

$$n = \frac{1 - \eta^2}{1 - 2\eta \cos \phi + \eta^2}$$

$$\kappa = \frac{2\eta \sin \phi}{1 - 2\eta \cos \phi + \eta^2} \quad [15]$$

For a detailed discussion, see the Further Reading section.

Internal Reflection Spectroscopy (ATR)

Internal reflection can only occur when the angle of the refracted beam θ_r is larger than the angle of incidence θ_i . This means, according to Snell's law (eqn [2]), that the refractive index of medium 2 must be smaller than that of medium 1 ($n_2 < n_1$). This is contrary to the situation in **Figure 1** where $n_2 > n_1$ was assumed. The region of total reflection begins when θ_r reaches 90° , that is at the critical angle of incidence θ_c . It follows from eqn [2] that

$$\sin \theta_c = \frac{n_2}{n_1} = n_{21} \quad [16]$$

It follows from eqns [2] and [16] for $\theta_i > \theta_c$ that $\sin \theta_r = \sin \theta_i / \sin \theta_c > 1$, resulting in a complex value for the corresponding cosine:

$$\cos \theta_r = \pm i n_{21} \sqrt{\sin^2 \theta_i - n_{21}^2} \quad [17]$$

The ratio r between internally reflected and incident electric field components is then obtained by introducing eqn [17] into eqn [1], resulting in

$$r_{||} = \frac{E_{r||}}{E_{i||}} = \frac{n_{21}^2 \cos \theta_i - i \sqrt{\sin^2 \theta_i - n_{21}^2}}{n_{21}^2 \cos \theta_i + i \sqrt{\sin^2 \theta_i - n_{21}^2}}$$

$$r_{\perp} = \frac{E_{r\perp}}{E_{i\perp}} = \frac{\cos \theta_i - i \sqrt{\sin^2 \theta_i - n_{21}^2}}{\cos \theta_i + i \sqrt{\sin^2 \theta_i - n_{21}^2}} \quad [18]$$

The corresponding equations for medium 2 are obtained by introducing eqn [17] into eqn [4], resulting in

$$t_{||} = \frac{E_{t||}}{E_{i||}} = \frac{2 \cos \theta_i}{n_{21} (\cos \theta_i - i \sqrt{\sin^2 \theta_i - n_{21}^2})}$$

$$t_{\perp} = \frac{E_{t\perp}}{E_{i\perp}} = \frac{2 \cos \theta_i}{\cos \theta_i - i n_{21}^2 \sqrt{\sin^2 \theta_i - n_{21}^2}} \quad [19]$$

Finally, it should be noted that incident electric fields undergo phase shifts in the ATR mode even if medium 2

is nonabsorbing. It follows from eqn [18] that

$$\tan \frac{\delta_{||}}{2} = \frac{\sqrt{\sin^2 \theta_i - n_{21}^2}}{n_{21}^2 \cos \theta_i}$$

$$\tan \frac{\delta_{\perp}}{2} = \frac{\sqrt{\sin^2 \theta_i - n_{21}^2}}{\cos \theta_i} \quad [20]$$

where $\delta_{||}$ and $\delta_{\perp}$ are the phase shifts per internal reflection (no absorption) of $||$ -polarized and $\perp$ -polarized incident light. Since the phase shifts and amplitudes are polarization dependent, linearly polarized incident light is elliptically polarized after an internal reflection. This phenomenon, however, does not hinder polarization measurement in the ATR mode.

Applications

Diffuse Reflectance

The geometry of a DR experiment is shown in **Figure 2**. The incident beam (I) is collimated to the sample S by means of the ellipsoidal mirror M_i . Two reflection mechanisms must be considered, specular reflection, R_s , and diffuse reflection, R_d . The former occurs at the surface and is governed by the Fresnel equations (eqns [1], [3] and [10–12]). As a consequence of anomalous dispersion, specular reflected light exhibits S-shaped intensity changes at the wavelengths of sample absorption. In contrast, diffuse reflected light exhibits absorption bands at frequencies observed also with transmitted light, but with intensities deviating significantly from those measured in a transmission experiment. The intensity of the DR spectrum may be described by the Bouguer–Lambert law (eqn [21]), the analogous expression to the Lambert–Beer law in transmission spectroscopy:

$$R_d = I_0 \exp(-\alpha \bar{d}) \quad [21]$$

where $\bar{d}$ is the mean penetrated layer thickness, that is the depth of light penetration into the surface layer which

Figure 2 Diffuse reflection experiment. M_i , M_r = ellipsoidal mirrors for incident and reflected light; S = sample; I, R_d , R_s = incident diffuse, and specular reflected beams, respectively. In the magnified circle a possible ray tracing through a surface particle is shown, demonstrating the formation of mixed diffuse and specular reflected light. $\bar{d}$ is the mean penetrated layer thickness according to the Bouguer–Lambert law (eqn [21]).

results in an intensity decrease by a factor of $1/e$, and α denotes the napierian absorption coefficient.

Diffuse reflectance infrared Fourier transform spectroscopy (DRIFT) has become a frequently used technique to obtain IR spectra from materials intractable by transmission spectroscopy. A number of high-performance reflection accessories are available from different manufacturers, allowing the detection of quantities down to the nanogram region. Nevertheless, DRIFT spectroscopy is confronted with two intrinsic problems: (1) the superposition of diffuse and specular reflected light (see **Figure 2**) which may lead to distorted line shapes and (2) the dependence of the mean penetration depth $\bar{d}$ on the absorption coefficient. $\bar{d}$ is found to be inversely proportional to the absorption coefficient α , thus leading to a certain levelling of the band intensities.

The disturbance by SR may be reduced considerably by technical means (trapping) on the reflection attachment. The resulting diffuse reflection spectrum then has to be corrected to correspond to the absorbance of a transmission spectrum. This mathematical procedure is generally performed according to the Kubelka–Munk theory. For a comprehensive and critical discussion of this theory the reader is referred to the Further Reading section.

Specular Reflection Spectroscopy

In specular reflectance, only light reflected off the front surface is collected (see **Figure 2**). The reflected energy is generally small ($<10\%$) for non-absorbing regions at normal or near-normal incidence. However, according to eqn [12], enhanced reflectance is observed in regions of sample absorption. As illustrated by **Figure 3**, radiation intensity is different to transmission intensity, since S-shaped bands result as a consequence of anomalous dispersion of the refractive index in the region of an

Figure 3 (a) Specular reflectance (SR) spectrum of a black acrylonitrile-butadiene-styrene polymer film measured at near-normal incidence, (b) Absorbance spectrum after data treatment of SR spectrum by a Kramers–Kronig transformation. Reproduced in part from Zachman G (1995) *Journal of Molecular Structure* 348: 453–456, with permission of Elsevier Science.

absorption band. As a typical example, the specular reflectance spectrum of a black plastic is shown in **Figure 3**.

Reflection Absorption Spectroscopy

Reflection Absorption Spectroscopy (RAS) at Near-normal Incidence

This is one of the most common and straightforward external reflection techniques. The IR beam is directed to the sample in the angular range $10\text{--}50^\circ$. The sample film must be on a reflective support. Under these conditions the RA spectrum is dominated by absorption since specular reflectance from the outer sample surface results in only 4–10% as shown in **Figure 4**. For this reason RA spectra resemble transmission spectra very closely. Accordingly, typical sample thicknesses are between 0.5 and $20\text{ }\mu\text{m}$.

RAS at Grazing Angle

Sensitivity at grazing angle is significantly enhanced with respect to near-normal reflectance and to transmission. The enhancement is explained by a polarization effect at the reflective surface. This effect is greatest for metal substrates and angles of incidence above 80° . As a general effect, $\perp$ -polarized incident light has a node at the interface (see the preceding). The resulting reflectance will be very weak as long as the layer thickness is significantly smaller than $\lambda/4$. Therefore, $\perp$ -polarized reflectance may be used as reference spectrum. $\parallel$ -Polarized incident light produces electric field components in the x - and z -directions. On metal surfaces, however, the x - and y -components vanish, but the z -component is

Figure 4 Specular reflectance calculated according to eqn [10]. Refractive indices: $n_1 = 1$ and $n_2 = 1.5$, $\parallel$, $\perp$ denote parallel- and perpendicular-polarized incident light. The Brewster angle, where $\rho_{\parallel} = 0$ for a non-absorbing medium, is calculated as $\theta_1 = \theta_B = 56.3^\circ$, according to $\tan \theta_B = n_{21}$.

significantly enhanced owing to interference of incident and reflected beams. Compared with near-normal incidence, RAS magnification may be by more than one order of magnitude, thus permitting monolayer spectroscopy by a single reflection. Detailed information on RAS techniques applied to study carbon monoxide (CO) adsorbed on metal surfaces can be found in the Further Reading section.

More recently, RAS at grazing angle has been applied successfully for *in situ* spectroscopy of lipid monolayers and proteins at the air–water interface of a Langmuir trough, using the water surface as reflector (see Further Reading section).

Polarization Modulation RAS

This technique makes use of the fact that $\perp$ -polarized incident light has a node at the reflecting interface resulting in zero absorbance at this point and nearly no absorbance of films significantly thinner than the quarter wavelength. Under these conditions, the $\perp$ -reflectance spectrum may be used as a reference spectrum for the $\parallel$ -reflectance spectrum. Since monolayer and submonolayer quantities of organic molecules result in low-intensity spectra, such measurements are susceptible to instrumental and environmental instabilities. This problem may be overcome by PM. For this purpose, a PEM is placed in the light path, leading to very fast periodic polarization changes of the incident light. The frequency range is 40–100 kHz, that is high enough to avoid interference's with the interferometer frequencies. Phase-sensitive demodulation of the PEM signal results in the interferogram of the difference between $\parallel$ - and $\perp$ -RA spectra, which is then normalized by division by the stationary response featuring the sum of $\parallel$ - and $\perp$ -mean reflectance according to

$$\frac{\Delta R}{R} = \frac{R_{\parallel} - R_{\perp}}{R_{\parallel} + R_{\perp}} \quad [22]$$

A description of an experimental set-up and of the relevant equations for PM-IRRAS can be found in the Further Reading section.

Instabilities are largely compensated because sample and reference spectra are measured and evaluated within one period, that is within 10–25 μ s. If applied in the IR region, this technique is referred to as PM-IRRAS.

It should be noted, however, that significant baseline problems may occur owing to different transmittance of $\parallel$ - and $\perp$ -polarized light by the spectrometer. This is demonstrated by the IRRAS data of a cadmium arachidate monolayer on a gold surface in **Figure 5**.

One should note that the usually intense absorption bands of CH_2 stretching, $\nu(\text{CH}_2)$ in the $2800\text{--}2950\text{ cm}^{-1}$ region and of CH_2 bending near 1470 cm^{-1} are very weak in the IRRAS spectrum in contrast to a corresponding

Figure 5 PM-IRRAS spectrum of an arachidic acid monolayer on a gold surface. The spectrum was normalized according to eqn [22]. It should be noted that only molecular vibration can be detected by IRRAS when the corresponding transition moment exhibits a component normal to the interface (z-direction). Reproduced in part with permission from Beccard B and Mapanowicz R (1995) *Nicolet Application Note AN-9542*. Madison, WI: Nicolet.

dipalmitoylphosphatidic acid (DPPA) monolayer ATR spectrum (see **Figure 9**). The reason is that IRRAS of thin layers on metallic surfaces offers only the electric field component normal to the interface, that is E_z , as already explained. The intensities of CH_2 stretching and CH_2 bending in **Figure 5** are consistent with hydrocarbon chains of arachidic acid (ArAc) aligned along the normal to the interface. The lack of E_x and E_y components, that is of an electric field component parallel to the interface, disables the determination of a tilt angle. In this respect, IRRAS is at a disadvantage with respect to ATR, the technique presented in the following section. Moreover, ATR allows significantly better baseline control, especially if a special technique such as SBSR or ME is applied.

ATR Spectroscopy

A number of interesting conclusions may be drawn from eqns [18] and [19]. First, calculation of the reflectance according to eqn [9] results in $\rho_{\parallel} = \rho_{\perp} = 1$ which means *total reflection*. However, if medium 2 is absorbing, one has to insert the complex refractive index (eqn [5]) into eqn [18], resulting in $\rho_{\parallel} \neq \rho_{\perp} < 1$ which means *attenuated total reflection (ATR)*.

Second, to obtain more information on the nature of this process, one may calculate the propagation of a plane-wave in medium 2 under the conditions of total reflection. The result for a non-absorbing medium 2 is that there is no transmittance normal to the interface, that is $\tau_z = 0$; however, there is an energy flux in the x, y -plane near the interface, that is $\tau_x, \tau_y \neq 0$. Hence, there is an electromagnetic wave beyond the interface, although the whole energy is totally reflected. This wave is referred to as *evanescent wave*. Straightforward calculation results in that the electric field strength of this wave

decreases exponentially with distance z from the interface, according to

$$E_{x,y,z} = E_{0x,y,z} \exp\left[-\frac{z}{d_p}\right] \quad [23]$$

The subscripts x, y, z stand for the electric field components of the evanescent wave in the corresponding directions. Subscript 0 denotes the value at $z = 0$ (interface in medium 2) and d_p is the so-called *penetration depth*, which results in

$$d_p = \frac{\lambda/n_1}{2\pi\sqrt{\sin^2\theta_i - n_2^2}} \quad [24]$$

where λ denotes the wavelength in vacuum and $\lambda/n_1 = \lambda_1$ is the wavelength in medium 1, that is, in the IRE. A typical ATR set-up is shown in **Figure 6**.

Hence, the penetration depth is the distance in the z -direction within which the electric field is decreased by a factor of $1/e$. This distance varies between a fraction of a micron and a few microns depending on the refractive indices of the IRE (e.g. $n_{\text{Ge}} = 4.0$, $n_{\text{ZnSe}} = 2.4$) and the medium 2 ($n_2 \approx 1.5$ for organic materials), as well as the angle of incidence. Harrick has given further practical details (see Further Reading section). As a consequence of Equations [23] and [24], the ATR spectrum features information on materials within a distance of one or a few d_p from the reflecting interface, resulting the highest sensitivity at the interface. Therefore, ATR spectroscopy is an optimum tool for *in situ* thin immobilized layer

analysis. For reviews on membrane spectroscopy the reader is referred to the Further Reading section.

Quantitative Analysis of ATR Spectra

The Concept of Effective Thickness

The concept of effective thickness was introduced by Harrick. The quantity d_e indicates the thickness of a sample that would result in the same absorbance in a hypothetical transmission experiment, as obtained with the genuine ATR experiment. This concept enables the straightforward application of the Lambert–Beer's law on ATR data according to

$$T = 10^{-Necd_e} = 10^{-A} \quad [25]$$

where $A = Necd_e$ denotes the absorbance resulting from N internal reflections. For an isotropic layer extending from $z = z_i$ to $z = z_f$ one obtains

$$d_e^{\text{iso}} = \frac{1}{\cos\theta_i} \frac{n_2}{n_1} \frac{d_p}{2} E_{02}^2 \times \left[\exp\left(-\frac{2z_i}{d_p}\right) - \exp\left(-\frac{2z_f}{d_p}\right) \right] \quad [26]$$

According to eqn [26] d_e turns out to be wavelength dependent via d_p . As a consequence, ATR spectra of bulk media generally show increasing intensity with increasing wavelength. However, if the thickness of the layer $d = z_f - z_i$ is small compared with d_p then eqn [26] reduces to eqn [27] which is independent of the wavelength. E_{02}^r denotes the relative electric field component at the reflecting interface of medium 2. For $z_i = 0$ one obtains

$$d_e^{\text{iso}} = \frac{1}{\cos\theta_i} \frac{n_2}{n_1} d E_{02}^r \quad [27]$$

For a bulk medium extending from $z_i = 0$ to $z_f = \infty$ eqn [26] results in

$$d_e^{\text{iso}} = \frac{1}{\cos\theta_i} \frac{n_2}{n_1} \frac{d_p}{2} E_{02}^r \quad [28]$$

A more detailed presentation including an approximate calculation of the effective thickness for intermediate layer thickness, that is $d \approx d_p$, and references for a rigorous application of the general formalism are given in the Further Reading section.

Relative Electric Field Components

The relative electric field components E_{02}^r are obtained from eqns [19] according to

$$\begin{aligned} E_{02,\parallel}^r &= \sqrt{(t_{\parallel}^*)^2}; \quad E_{02,\perp}^r = \sqrt{(t_{\perp}^*)^2} \\ E_{02,x}^r &= E_{02,\parallel}^r \cdot \cos\theta_i; \quad E_{02,z}^r = E_{02,\parallel}^r \cdot \sin\theta_i \\ E_{02,y}^r &= E_{02,\perp}^r \end{aligned} \quad [29]$$

Figure 6 ATR set-up. Optical and structural features are related to the IRE fixed-coordinate system x, y, z . $E_{\parallel}$ and $E_{\perp}$ denote the parallel- and perpendicular-polarized electric field components of the light incident to the IRE under the angle θ_i . $E_{\parallel}$ results in the E_x and E_z components of the evanescent wave, while $E_{\perp}$ results in the E_y component. $\mathbf{m}$ denotes the unit vector in the direction of the transition dipole moment vector of a given vibrational mode, and m_x, m_y, m_z are the corresponding components in the IRE coordinate system. $\mathbf{m}$ goes off at an angle α with respect to the z -axis and the projection of $\mathbf{m}$ to the xy -plane goes off at an angle ϕ with respect to the x -axis. Reproduced, from Fringeli UP, et al. (1998) *AIP Conference Proceedings* 430: 729–747, with permission of the American Institute of Physics.

Explicit expressions of eqns [29] for thin films and bulk media can be found in references in the Further Reading section.

Validity of the Effective Thickness Concept

Since the effective thickness concept permits the application of Lambert–Beer’s law to ATR data, experimental validation may be performed easily by comparing spectra of the same sample measured by both, ATR and transmission (T). As long as the results do not differ significantly from each other the formalism described earlier is considered to be applicable. ATR and T measurements with aqueous solutions of Na₂SO₄ have shown that at a 1 M concentration Lambert–Beer’s law is still fulfilled for the very intense SO₄²⁻ stretching band at 1100 cm⁻¹. Even for the strong H₂O bending [$\delta(\text{H}_2\text{O})$] band of liquid water at 1640 cm⁻¹ the integral molar absorption coefficients determined by ATR with a germanium IRE at an angle of incidence of $\theta_i = 45^\circ$ was found to be equal to T data within the experimental error. However, a few per cent deviations were found when peak values of the absorbance were used to determine the molar absorption coefficient. The latter indicates the onset of band distortion, a phenomenon well known in ATR spectroscopy under conditions of strong absorption. This finding is in accordance with calculations by Harrick using Fresnel’s equations with complex refractive indices. For Ge in contact with liquid water and $\theta_i = 45^\circ$ the analysis resulted in an upper limit of the absorption coefficient $\alpha_{\max} \approx 1000 \text{ cm}^{-1}$. The concept of effective thickness as described earlier may be considered to be valid for $\alpha < \alpha_{\max}$. For organic compounds this condition is generally fulfilled. In the case of $\delta(\text{H}_2\text{O})$ of liquid water, however, the absorption coefficient results in $\alpha = \varepsilon(1640 \text{ cm}^{-1})c = 1.82 \times 10^4 \text{ cm}^2 \text{ mol}^{-1} \times 5.56 \times 10^{-2} \text{ mol cm}^{-3} = 1011.9 \text{ cm}^{-1}$, which indicates that the limit of validity of the approach is reached, in complete accordance with experimental data mentioned earlier. Furthermore, it turned out that the anomalous dispersion in the range of strong water absorption bands should be taken into account if sample absorption within this range is analysed quantitatively.

Quantitative Analysis Taking Sample Absorption and Thickness into Account

The validity of Harrick’s weak absorber approximations has been checked by comparison with the general thickness- and absorption-dependent model. It was found that the formalism depicted in the preceding section may be used for film thicknesses up to 20 nm. Especially if the film is in contact with a third bulk medium, for example water, the deviation between accurate and approximate calculation of relative electric field components according to eqn [29] was found to be below 3%, that is within the error of most experiments. A comprehensive description of ATR spectroscopy of polymers using the general formalism can be found in the Further Reading section.

Since quantitative analysis of ATR data by the general formalism is very cumbersome, the use of more tractable approximations is recommended if possible. One possibility is the weak absorber approximations described in the preceding text; another approach was derived for the study of electrochemical reactions by ATR spectroscopy.

For more general information on quantitative methods and applications of ATR spectroscopy, see the Further Reading section.

Orientation Measurements

Considering a transition dipole moment $\mathbf{M}$ associated with a vibrational mode of a given molecule and the electric field $\mathbf{E}$, responsible for vibrational excitation, the magnitude of light absorption depends on the mutual orientation of these two vectors according to eqn [30], which is the basis for orientation measurements. M_x , M_y and M_z denote the components of the transition dipole moment in the IRE fixed coordinate system shown in **Figure 6**.

$$\begin{aligned} A &= (\mathbf{E} \cdot \mathbf{M})^2 \\ &= |\mathbf{E}|^2 \cdot |\mathbf{M}|^2 \cdot \cos^2(\mathbf{E}, \mathbf{M}) \\ &= (E_x M_x + E_y M_y + E_z M_z)^2 \end{aligned} \quad [30]$$

It is usual to work with dimensionless relative intensities instead of absolute intensities to get rid of physical and molecular constants, for example the magnitude of the transition moment. Introducing the so-called dichroic ratio R , the absorbance ratio obtained from spectra measured with $\parallel$ - and $\perp$ - polarized incident light, that is

$$\begin{aligned} R &= \frac{A_{\parallel}}{A_{\perp}} = \frac{d_{e,\parallel}}{d_{e,\perp}} \\ &= \frac{E_x^2 \langle m_x^2 \rangle + E_z^2 \langle m_z^2 \rangle + 2E_x E_z \langle m_x m_z \rangle}{E_y^2 \langle m_y^2 \rangle} \end{aligned} \quad [31]$$

where A and d_e denote absorbance and effective thickness relative to $\parallel$ - and $\perp$ - polarized incident light, respectively. E_x , E_y and E_z denote the relative electric field components according eqn [29]. $\langle m_x^2 \rangle$, $\langle m_y^2 \rangle$, $\langle m_z^2 \rangle$ and $\langle m_x m_z \rangle$ are ensemble mean values of the components of the unit vector in the direction of the transition dipole moment, see **Figure 6**. $\langle m_x m_z \rangle = 0$ for uniaxial orientation, for example isotropic distribution around all relevant orientation axes. On substitution of the unit vector components according to the geometry depicted in **Figure 6**, one obtains for the dichroic ratio

$$R^{\text{ATR}} = \frac{E_x^2}{E_y^2} + 2 \frac{E_z^2}{E_y^2} \frac{\langle \cos^2 \alpha \rangle}{1 - \langle \cos^2 \alpha \rangle} \quad [32]$$

where $\langle \cos^2 \alpha \rangle$ denotes the mean square cosine of the angle between the transition moment and the normal to

the interface. This quantity is accessible via two measurements, one with $\parallel$ -polarization and the other with $\perp$ -polarized incident light, resulting in R . The relative electric field components are available from Fresnel's eqns [19] with eqn [29]. For an isotropic sample, $\langle \cos^2 \alpha \rangle_{\text{iso}} = 1/3$. Insertion of this value into eqn [32] results in

$$R_{\text{iso}}^{\text{ATR}} = \frac{E_x^2 + E_z^2}{E_y^2} \quad [33]$$

It should be mentioned that an isotropic sample results in $R=1$ in transmission but, according to eqn [33], not in ATR, where $R_{\text{iso}}^{\text{ATR}} \neq 1$. As an example, for total reflection with a bulk material 2 and $\theta_i = 45^\circ$, one obtains $R_{\text{iso}}^{\text{ATR}} = 2.0$ irrespective of n_1 and n_2 , except $n_1 > n_2$.

The segmental order parameter S_{seg} is frequently used to characterize molecular ordering, for example to describe the fluctuation of a functional group in a molecule via the polarized absorption bands of a typical group vibration. For uniaxial orientation the order parameter is defined according to

$$S_{\text{seg}} = \frac{3}{2} \langle \cos^2 \alpha \rangle - \frac{1}{2} \quad [34]$$

Thus, if the ATR geometry and the optical constants of the system are known, then S_{seg} may be determined measuring the dichroic ratio R of a given absorption band, followed by the calculation of the mean square cosine $\langle \cos^2 \alpha \rangle$ and inserting this value into eqn [34]. A typical example is discussed later.

For more details and examples of application the reader is referred to the Further Reading section.

Determination of Surface Concentration

The effective thickness as indicated by eqns [26]–[28] holds for isotropic samples. Modification for oriented samples results

$$\begin{aligned} d_{ex} &= 3 \langle m_x^2 \rangle d_{ex}^{\text{iso}} = \frac{3}{2} (1 - \langle \cos^2 \alpha \rangle) d_{ex}^{\text{iso}} \\ d_{ey} &= 3 \langle m_y^2 \rangle d_{ey}^{\text{iso}} = \frac{3}{2} (1 - \langle \cos^2 \alpha \rangle) d_{ey}^{\text{iso}} \\ d_{ez} &= 3 \langle m_z^2 \rangle d_{ez}^{\text{iso}} = 3 \langle \cos^2 \alpha \rangle d_{ez}^{\text{iso}} \end{aligned} \quad [35]$$

From eqn [25] and the relation $d_{e\parallel} = d_{ex} + d_{ez}$ and $d_{e\perp} = d_{ey}$ one obtains for the surface concentration Γ .

$$\begin{aligned} \Gamma = c \cdot d &= \frac{d \cdot A_{\parallel}}{v \cdot N \cdot d_{e\parallel} \cdot \varepsilon} = \frac{d \cdot \int A_{\parallel} d\tilde{\nu}}{v \cdot N \cdot d_{e\parallel} \cdot \int \varepsilon d\tilde{\nu}} \\ &= \frac{d \cdot A_{\perp}}{v \cdot N \cdot d_{e\perp} \cdot \varepsilon} = \frac{d \cdot \int A_{\perp} d\tilde{\nu}}{v \cdot N \cdot d_{e\perp} \cdot \int \varepsilon d\tilde{\nu}} \end{aligned} \quad [36]$$

where $A_{\parallel}$ and $A_{\perp}$ denote the absorbance measured with parallel- and perpendicular- polarized incident light,

respectively, ε is the molar absorption coefficient, v denotes the number of equal functional groups per molecule and N is the number of active internal reflections. It should be noted that eqn [36] holds for peak absorbance and integrated absorbance, provided that the corresponding molar absorption coefficients are used.

Special Experimental ATR Techniques

SBSR Technique

Most FTIR spectrometers are working in the SB mode. As a consequence a single-channel reference spectrum has to be stored for later conversion of single-channel sample spectra into transmittance and absorbance spectra. This technique suffers inaccuracy owing to drifts resulting from the instrument, the sample or atmospheric absorption. To eliminate these unwanted effects to a great extent, a ATR attachment has been constructed, converting a single-beam instrument into a pseudo-double-beam instrument. The principle features of this attachment are depicted in **Figure 7**. As usual, a convergent IR beam enters the sample compartment. However, the focal point is now displaced from the centre of the sample compartment by means of the planar mirrors M1 and M2 to the new position F. The off-axis parabolic mirror M3 performs a conversion of the divergent beam into a parallel beam with fourfold reduced cross-section. This beam is focused to the entrance face of a trapezoidal MIRE by a cylindrical mirror M4. Therefore, the ray propagation in the MIRE is still parallel to the direction of light propagation (x -axis), enabling subdivision of the two reflective faces (x, y -planes) of the MIRE alongside at half-height. One half of the MIRE is then used for the sample (S) and the other one for the reference (R). Both S and R were encapsulated by flow-through cuvettes, independently accessible by liquids or gases. This principle is referred to as the SBSR technique.

SBSR absorbance spectra are calculated from sample and reference single-channel spectra which have been measured with a very short mutual time delay. A most favourable benefit of SBSR technique is that no wasted time for purging is required before starting a measurement after closing the sample compartment. Moreover, the whole sequence of single-channel spectra in the S and R channels is also available, allowing reconstruction of the history of each channel at any time by conventional data handling.

Modulated Excitation ME Spectroscopy and 2D IR Spectroscopy

Change of any external thermodynamic parameter generally exerts a specific influence on the state of a chemical system. The system response will be relaxation from the initial state (e.g. an equilibrium) to the final state (a new equilibrium state or a stationary state). In the case of a

Figure 7 Single-beam sample reference (SBSR) ATR attachment. (a) The focus in the sample compartment is displaced to the position F by the planar mirrors M1 and M2. The off-axis parabolic mirror M3 produces a parallel beam with a diameter of 1 cm, that is half of the height of the MIRE. The cylindrical mirror M4 focuses the light to the entrance face of the MIRE. M5, which has the same shape as M4, reconverts to parallel light directing it via the planar mirror M6 through the polarizer POL, and it is then being focused to the detector DET by the off-axis parabolic mirror M7. (b) Alternating change from sample to reference is performed by computer-controlled lifting and lowering of the ATR cell body. Reproduced, from Fringeli UP et al. (1998) *AIP Conference Proceedings* 430: 729–747, with permission of the American Institute of Physics.

periodic change (modulation) of the parameter, the system response will also be periodic with angular frequency ω , relaxing from the initial state to a stationary state. All absorption bands of the spectrum which result from stimulated molecules or parts of them will be labelled by the frequency ω . As a consequence, it is possible to separate the modulated response of a system from the stationary response, resulting from parts of the system that were not affected by ME as well as from the background. More-over, if the kinetics of the stimulated process is in the same time range as the period of external excitation, phase lags and damped amplitudes will result. Both depend characteristically on the stimulation frequency, and therefore one can derive relevant information on the reaction scheme and the kinetics of the stimulated process (see also caption to **Figure 8**).

A variety of ME experiments have been reported. (1) Temperature ME of poly-L-lysine was used to study induced periodic secondary structural changes as well as the sequence of transients. (2) The classical ATR set-up (see **Figure 6**) facilitates the application of electric fields to immobilized thin films, such as biomembrane assemblies or to bulk materials such as liquid crystals, since a Ge ATR plate, supporting the membrane, may be used as one electrode, and the back-wall of the cuvette as counter electrode. (3) Hydration modulation was used to detect hydration sites of model membranes, (4) ME by UV radiation permitted kinetic studies of photoinduced chemical reactions and (5) ME by chemical substrates is a further versatile method to study chemically induced conformational changes of a sample immobilized to the MIRE. For that purpose, two computer-controlled pumps are used for periodic exchange of the liquid (water) environment of the sample in a flow-through cell. An example demonstrating the sensitivity and high quality of background compensation of ME techniques is presented later. The principles of ME spectroscopy are depicted schematically in **Figure 8**.

2D FTIR Spectroscopy

Absorption bands in a set of modulation spectra that exhibit equal phase shifts with respect to the external stimulation are considered to be correlated. 2D correlation analysis is a statistical graphical means to visualize such a correlation in a 2D plot. Consequently, phase-resolved modulation spectra are data of a higher level and unambiguously allow a more direct and accurate evaluation. 2D plots look attractive, but one should be aware that the information content is lower than that of the underlying modulation spectra, first because band overlapping may result in inadequate phase information, and second because 2D spectra are affected much more by baseline errors than the original modulation spectra. A comprehensive discussion can be found in the Further Reading section.

Sensitivity of ATR Spectroscopy

Sensitivity of Stationary ATR Measurements

Commercial multiple internal reflection elements (MIRE) permit up to 50 internal reflections. This is generally enough for thin-layer spectroscopy in the nanometre or even subnanometre region. As an example, **Figure 9** shows a DPPA monolayer, that is a lipid monolayer of approximately 2 nm thickness, which has been transferred from approximately the air–water interface to a germanium MIRE by means of the Langmuir–Blodgett technique.

The dominant bands in **Figure 9** result from the stretching vibrations of 28 CH_2 groups of the two saturated hydrocarbon chains of the DPPA molecule. Looking at three resolved weaker bands gives an impression of the

Figure 8 Schematic set-up for modulated excitation (ME) experiments. A periodic excitation is exerted on the sample with frequency ω . The sample response $S(t)$, as sensed by IR radiation, contains the frequency ω and higher harmonics at wavelengths that are significant for those parts of the sample that have been affected by the stimulation. Selective detection of the periodic sample responses is performed by phase-sensitive detection (PSD), resulting in the DC output and A_n of fundamental ω ($n=1$) and their harmonics $n\omega$ ($n=2, 3, \dots$), as well as the phase shifts ϕ_n between the n th harmonic and the stimulation. This phase shift is indicative of the kinetics of the stimulated process and of the underlying chemical reaction scheme. Since the PSD output A_n ($n=1, 2, \dots, n$; frequency $n\omega$) is proportional to $\cos(\phi_n - \phi_{n,PSD})$, absorption bands featuring the same phase shift ϕ_n are considered to be correlated, i.e. to be representative of a population consisting of distinct molecules or molecular parts. $\phi_{n,PSD}$ is the operator-controlled PSD phase setting. Because of the cosine dependence, different populations will have their absorbance maxima at different $\phi_{n,PSD}$ settings, thus allowing selective detection. Moreover, since in the case that $0.1 < \omega\tau_i < 10$ (τ_i denotes the i th relaxation time of the system), ϕ_n becomes ω dependent, $\phi_n = \phi_n(\omega)$. The spectral information can then be spread in the $\phi_{n,PSD} - \omega$ plane, resulting in a significant enhancement of resolution with respect to standard difference spectroscopy and time-resolved spectroscopy.

Figure 9 Parallel (||) and perpendicular ($\perp$) polarized ATR absorbance spectra of a dipalmitoylphosphatidic acid (DPPA) monolayer transferred at 30 mN m^{-1} from the aqueous subphase (10^{-4} M CaCl_2) to a germanium multiple internal reflection element (MIRE). Spectra were obtained from the dry monolayer in contact with dry air. A surface concentration of $\Gamma = 3.93 \times 10^{-10} \text{ mol cm}^{-2}$ was calculated by means of eqn [36] using the dichroic ratio of the symmetric CH_2 stretching vibration at 2850 cm^{-1} with respect to a linear baseline (B), resulting in $R^{\text{ATR}}[\nu^s(\text{CH}_2)] = 0.923$. Angle of incidence $\theta_i = 45^\circ$; number of equal functional groups $\nu = 28$; number of active internal reflections $N = 39$.

absorbance to be expected from a monomolecular coverage by functional groups of medium or weak molar absorption. The first is the terminal methyl group of the hydrocarbon chains. The antisymmetric stretching vibration, $\nu_{\text{as}}(\text{CH}_3)$, absorbs at $\sim 2960 \text{ cm}^{-1}$. As concluded from **Figure 9**, this monolayer results in a peak absorbance

of approximately 6 mAU. A weaker band is observed near 1420 cm^{-1} and may be assigned to the bending vibration of the α -methylene groups of the hydrocarbon chains, $\delta(\alpha\text{-CH}_2)$. Thus, an approximate monolayer of $\alpha\text{-CH}_2$ groups results in an absorbance of only about 1 mAU. Third, a monolayer of phosphate head groups results in more

intense absorption bands because of the larger transition dipolemoment of the polar group. The corresponding absorbances of PO_3 stretching vibrations in the range $1000\text{--}1250\text{ cm}^{-1}$ are between 5 and 10 mAU. It is concluded that conventional ATR measurements may allow significant access to bands of approximately 0.2–0.5 mAU, which correspond to 20–50% of a monolayer of weak absorbers.

Quantitative Analysis of Stationary ATR Spectra

The DPPA monolayer spectra shown in **Figure 9** are now used to demonstrate the ease of application of the formalism for quantitative analysis of ATR spectra presented earlier.

Dichroic Ratio of Symmetric CH_2 Stretching

The dichroic ratio according to eqn [32] was calculated from the integrated absorbances of the symmetric CH_2 stretching bands, $\nu_s(\text{CH}_2)$, using linear baselines as marked in **Figure 9** with lower and upper limits at 2828 and 2871 cm^{-1} , respectively. The corresponding integrals were found to be $\int A_{\parallel} d\tilde{\nu} = 0.381\text{ cm}^{-1}$, and $\int A_{\perp} d\tilde{\nu} = 0.413\text{ cm}^{-1}$, resulting in $R^{\text{ATR}} = 0.923$. This is the relevant experimental quantity.

Mean Orientation of Hydrocarbon Chains

Uniaxial orientation, that is isotropic distribution of DPPA around the z -axis, is assumed. The mean square cosine of the angle between the transition dipole moments of $\nu_s(\text{CH}_2)$ of the whole population of CH_2 groups of the molecule (28 groups in hydrocarbon chains, 1 in the glycerol part, slightly shifted in frequency) can be calculated from eqn [32], resulting in eqn [37].

$$\langle \cos^2 \alpha \rangle = \frac{(R^{\text{ATR}} - E_x^2/E_y^2)(E_y^2/E_z^2)}{2 + (R^{\text{ATR}} - E_x^2/E_y^2)(E_y^2/E_z^2)} \quad [37]$$

The squares of relative electric field components at the interface ($z = 0$) in medium 2 as calculated from eqn [29] for $\theta_i = 45^\circ$, $n_1 = 4.0$ (germanium), $n_2 = 1.5$ (DPPA monolayer) and $n_3 = 1.0$ (dry air) result in $E_{ox,2}^2 = 1.991$, $E_{oy,2}^2 = 2.133$ and $E_{oz,2}^2 = 0.450$. It follows that $E_{o\parallel,2}^2 = E_{ox,2}^2 + E_{oy,2}^2 = 2.441$ and $E_{o\perp,2}^2 = E_{oz,2}^2 = 0.450$. The dichroic ratio for an isotropic film under these conditions would result in, according to eqn [33], $R_{\text{iso}}^{\text{ATR}} = 1.144$. Explicit equations for relative electric components calculated by means of Harrick's weak absorber approximation can be found in the Further Reading section.

Introducing the experimental value of R^{ATR} and the calculated squares of relative electric field components into eqn [37], one obtains for the mean square cosine of the angle between the transition moment of $\nu_s(\text{CH}_2)$ and the z -axis $\langle \cos^2 \alpha \rangle = -0.025$. This value should not be negative because its minimum is zero; however, since it is

small, it is considered to be within experimental and predominately systematic errors. Therefore, is set $\langle \cos^2 \alpha \rangle = 0$, resulting in $\alpha = 90^\circ$. This result requires that all methylene groups of the hydrocarbon chains assume an all-*trans* conformation and, moreover, all hydrocarbon chains are aligned normal to the MIRE, that is parallel to the z -axis (tilt angle 0°). The exact wave-number of the symmetric stretching vibration of the CH_2 group in glycerol is not known. However, overlapping with $\nu_s(\text{CH}_2)$ of the hydrocarbon chains is probable. Consequently, the bisector of the glycerol CH_2 group may also be concluded to be predominately parallel to the x, y -plane.

Mean Order Parameter of CH_2 Groups

The mean segmental order parameter resulting from eqn [34] is found to be $\bar{S}_{\text{seg}}[\nu_s(\text{CH}_2)] = -\frac{1}{2}$. This value is representative of a perfectly ordered molecular entity with isotropic arrangement of transition dipole moments around the z -axis and perfect parallel alignment to the interface (x, y -plane). It should be noted that for $\langle \cos^2 \alpha \rangle = 1$, that is transition moments perfectly aligned normal to the interface (z -axis), eqn [34] results in the upper limit $\bar{S}_{\text{seg}} = 1$. Lipids in natural biomembranes consist of a considerable amount of unsaturated hydrocarbon chains. Since double bonds cause unavoidably *gauche* defects in elongated hydrocarbon chains, which leads to a reduced chain ordering, $\bar{S}_{\text{seg}}[\nu_s(\text{CH}_2)]$ is increased, reaching zero for an isotropic chain arrangement, since $\langle \cos^2 \alpha \rangle = 1/3$ in this case.

It should be noted that the determination of order parameters of individual methylene groups in the hydrocarbon chains requires generally selective deuteration. In this respect, comprehensive deuterium NMR work should be mentioned (see Further Reading section).

A more general case of sample geometry is that of a transition moment being inclined by an angle Θ with respect to the molecular axis a and isotropically distributed around a . Furthermore, the molecular axis a forms an angle γ with respect to the tilt axis t , and is isotropically distributed around it, and finally, the axis t forming a tilt angle δ with the z -axis and is isotropically distributed around it. In this case, the segmental order parameter, for example $S_{\text{seg}}[\nu_s(\text{CH}_2)]$, may be expressed as superposition of three uniaxial orientations according to

$$\begin{aligned} S_{\text{seg}} &= \left(\frac{3}{2} \langle \cos^2 \delta \rangle - \frac{1}{2} \right) \cdot \left(\frac{3}{2} \langle \cos^2 \gamma \rangle - \frac{1}{2} \right) \\ &\quad \times \left(\frac{3}{2} \langle \cos^2 \Theta \rangle - \frac{1}{2} \right) \\ &= S_\delta \cdot S_\gamma \cdot S_\Theta \end{aligned} \quad [38]$$

The angles δ , γ and Θ may be distinct or fluctuating (partly or all), describing a microcrystalline ultrastructure

(MCU) and a liquid crystalline ultra-structure (LCU), respectively. S_γ is referred to as the molecular order parameter S_{mol} .

Applying eqn [38] to the DPPA monolayer under discussion, one obtains: $S_\delta = 1$, $S_\gamma = 1$, $S_\Theta = -\frac{1}{2}$, meaning no tilt ($\delta = 0$), molecular axis (hydrocarbon chain) normal to the interface ($\gamma = 0$), and transition dipole moment normal to the molecular axis ($\Theta = 90^\circ$).

Surface Concentration and Area per Molecule

The surface concentration may be calculated using eqn [36]. The following additional information is required: (1) the integrated molar absorption coefficient related to a linear baseline from 2828 to 2871 cm^{-1} (see **Figure 9**) was $\int \epsilon d\tilde{\nu} = 5.7 \times 10^5 \text{ cm mol}^{-1}$, (2) the real thickness of the layer was assumed to be $d = 2.5 \text{ nm}$, (3) the number of equal functional groups $\nu = 28$ and (4) the effective thicknesses d_e for parallel- or perpendicular- polarized incident light, which were calculated from eqns [27] and [35], resulted in $d_{e,\parallel} = 3.97 \text{ nm}$ and $d_{e,\perp} = 4.30 \text{ nm}$. The mean surface concentration was found to be $3.93 \times 10^{-10} \text{ mol cm}^{-2}$, corresponding to a molecular cross-section of 0.427 nm^2 per molecule ($42.3 \text{ \AA}^2$ per molecule). This value leads to the conclusion that the two hydrocarbon chains of a DPPA molecule predominantly determine the area per molecule, since the cross-section of an elongated hydrocarbon chain is $20\text{--}21 \text{ \AA}^2$.

Conclusions

Quantitative analysis, including orientation measurements, has been shown to be straightforward when the formalism based on Harrick's weak absorber approximation is applied. For thin adsorbed layers, such as the DPPA monolayer under discussion, the results are fairly good. Application to bulk materials may introduce systematic errors as discussed in the preceding text. If the weak absorber approximation is still to be applied, one should take care to work with an angle of incidence which is at least 15° larger than the critical angle, to avoid significant band distortions. In many cases it is possible to use quantitative data from transmission experiments to check the validity of the formalism applied to ATR data.

A general critical aspect concerning the baseline selection should be mentioned. A linear tangential baseline has been used for quantitative analysis of the symmetric CH_2 stretching vibration of DPPA (see **Figure 9**). Obviously the correct baseline is lower, that is the integrated absorbances used for analysis are systematically too small. The reason for this procedure is only to permit good reproducibility. While the determination of the dichroic ratio is indifferent with respect to the choice of the baseline, it is mandatory to use integrated or peak molar absorption coefficients which have been determined under

the same conditions. Even then deviations in the range of several per cent may occur among different operators.

Finally, it should be noted that ATR spectroscopy allows very good background compensation, when adequate equipment is used.

Sensitivity of ME ATR Spectroscopy

An impression of the sensitivity of stationary measurements was given the last but one section. A limit of 0.2 mAU is suggested. This limit is beaten by one order or magnitude when the ME technique is applied. As mentioned earlier, the sample must fulfil the condition of a reversible stimulation by a periodically altered external thermodynamic parameter. Here, the excellent sensitivity and instrumental stability will be demonstrated, for example, with a chemical modulation experiment performed in liquid water, a very strong absorber in the 3400 and 1640 cm^{-1} region.

In order to study the influence of immobilized charges on a lipid model membrane, an ArAc bilayer was prepared on a germanium MIRE by means of the Langmuir–Blodgett (LB) technique. The MIRE was transferred in the hydrated state from the LB trough into a flow-through cell and kept in permanent contact with an aqueous buffer solution. Since the carboxylic acid groups of the second monolayer were facing the aqueous phase, the degree of protonation could be controlled via the environmental pH. A periodic pH modulation between pH 3 and 10 induced a periodic protonation and deprotonation of the carboxylic acid group. It should be noted that the first ArAc LB layer was attached by head to the Ge MIRE. Obviously, this binding was so special that typical absorption bands of the carboxylic acid groups were not visible in the spectrum. Therefore, one may assume that the head group signals shown in **Figure 10** result predominately from the outer monolayer of ArAc. The stationary spectral intensity is comparable to that of the DPPA monolayer shown in **Figure 9**. Moreover, one should note that the experiments were performed in H_2O , where in the 1640 and 3400 cm^{-1} regions there is very low spectral energy available, favouring perturbations by incomplete background compensation.

In this context, only the sensitivity and selectivity of ME techniques will be discussed. A comprehensive presentation and analysis of polarized pH modulation spectra will be given elsewhere.

Sensitivity of ME-Spectroscopy

Taking the pH-modulated spectrum shown in **Figure 10** as a typical example, one may estimate the sensitivity by comparing the most intense ME spectra ($\phi_{\text{PSD}} = 60^\circ / \phi_{\text{PSD}} = 90^\circ$, the maximum is expected at $\phi_{\text{PSD}} \approx 75^\circ$, consequently, $\phi_{\text{PSD}} \approx 165^\circ$ should result intensity zero) with the lowest intensity ME spectrum at $\phi_{\text{PSD}} = 0^\circ$. To check the S/N ratio, the $\phi_{\text{PSD}} = 0^\circ$ spectrum was

expanded 25 times in the CH_2 wagging region and is plotted as a dashed inset in **Figure 10**. The ordinate scaling factor for the zoomed spectrum is 4.0×10^{-5} . Comparing it with the other ME spectra (scaling factor 1.0×10^{-3}) one can conclude that bands as weak as 1.0×10^{-5} AU are still detectable.

Selectivity of pH ME

The highest selectivity of ME spectroscopy is achieved if the stimulation frequency ω and the kinetics of the stimulated process are matched, that is if $0.1 < \omega\tau_i < 10$, where τ_i denotes the i th relaxation time of the system. τ_i is a function of the rate constants involved in the stimulated process. Under these conditions, significant ω -dependent phase shifts are expected, resulting in $\phi_i = \arctan(-\omega\tau_i)$ for a linear system. Consequently, a molecular or conformational population represented by the relaxation time τ_i exhibits maximum absorbance in the ME spectrum at a PSD phase setting $\phi_i = \phi_{\text{PSD}}$, thus allowing selective detection and kinetic analysis by means of phase-resolved ME spectra. Moreover, ω acts as an additional experimental degree of freedom in this context, since information on selectivity and kinetics can be spread in the ω/ϕ_{PSD} plane which is more selective

than the unidirectional information resulting from conventional relaxation measurements.

In the actual case of pH modulation exerted on a monolayer of ArAc, there is no phase resolution observed, owing to the long modulation period of $\tau_m = 16$ min, that is no kinetic information is available. However, unambiguous discrimination between the protonated and deprotonated populations is possible. Only one characteristic example will be given here. The most prominent band from the protonated state is the C=O stretching vibration $\nu(\text{COOH})$ of the carboxylic acid group near 1700 cm^{-1} . All other bands in the ME spectrum that have the same phase belong to the protonated population, whereas the remaining bands featuring opposite sign are members of the deprotonated population. Consequently, if no phase resolution is achieved, ME spectra reduce to difference spectra, which, however, have a considerably better background and instability compensation than conventional difference spectra, since corresponding sample and reference spectra are measured and evaluated/accumulated within each period of stimulation.

Consider now the wagging region $\gamma_w(\text{CH}_2)$ of the spectra shown in **Figure 10**. The wagging motion $\gamma_w(\text{CH}_2)$ is described as in-phase displacement of both H atoms through the H-C-H plane of a methylene group, where the

Figure 10 pH-modulated excitation (ME) of an arachidic acid (ArAc) bilayer attached to a germanium multiple internal reflection element (MIRE). ME was performed by pumping alternatively two buffer solutions (100 mM NaCl, pH 3 and 100 mM NaCl, pH 10) through the ATR cuvette with a modulation period of $\tau = 16$ min. $T = 10^\circ \text{C}$. Upper trace A_0 ; stationary spectrum of a protonated ArAc layer for comparison with modulation spectra. Traces A_1 ; modulation spectra at PSD phase settings $\phi_{\text{PSD}} = 0, 30, \dots, 180^\circ$. The 180° spectrum corresponds to the 0° spectrum with opposite sign, because the PSD output is proportional to $\cos(\phi - \phi_{\text{PSD}})$, see also **Figure 8**. ϕ denotes the phase difference between a given band and the stimulation. Owing to the long period of $\tau_m = 16$ min, the observed bands in the modulation spectra exhibit only two resolved ϕ values, which are 180° apart, as a consequence of the fact that the chemical relaxation time of protonation/deprotonation of ArAc is much shorter than the stimulation period. To demonstrate the excellent S/N ratio, the ordinate of the weakest modulation spectrum has been expanded in the CH_2 wagging region by a factor of 25, that is the ordinate scaling factor for the dashed spectrum results in 4.0×10^{-5} (see text).

C atom remains predominately in place. In an all-*trans* hydrocarbon chain the transition dipole moment of $\gamma_w(\text{CH}_2)$ is expected to be parallel to the chain direction. Deviations may occur, however, from coupling with a polar end group. In the stationary absorbance spectrum A_0 , one can observe nine weak bands between approximately 1180 and 1320 cm^{-1} . This sequence results from concerted wagging vibrations of all methylene groups in a hydrocarbon chain with an all-*trans* conformation. According to IR selection rules one has to expect $n/2$ IR-active vibrations for an even number n of CH_2 groups in an all-*trans* conformation. ArAc has 18 CH_2 groups per chain, resulting in the above-mentioned sequence of nine bands in accordance with theory. Since these bands are found to be in phase with $\nu(\text{COOH})$, one can conclude that deprotonation of COOH is paralleled by reversible disordering of the chain structure, most probably by introducing *gauche* defects.

Finally, it should be mentioned that $\gamma_w(\text{CH}_2)$ belongs to the group of weak absorption bands. One can conclude, therefore, that ME IR ATR spectroscopy allows significant quantitative studies on a molecular level with submonolayer quantities of weak absorbers.

Introduction

A remarkable range of fluorescence spectroscopy techniques has been developed in the last fifty years to characterize fundamental properties of biological systems. The rapid progress over this period has led to strategies for monitoring events that transpire on the femtosecond time scale, for discerning features smaller than the Rayleigh resolution limit of light and for detecting individual molecules. More routinely, fluorescence spectroscopy has provided invaluable insights into the structure, function and concentrations of macromolecules, small molecules, lipids and inorganic ions. Moreover, fluorescence analysis of living systems has begun to reveal directly how these biochemicals function and interact *in situ*. The initial section of this article presents an overview of the measurement formats used in fluorescence studies of biochemical systems. In the sections that follow, the application of diverse spectroscopic techniques to the study of biomolecular systems is examined, considering both the properties and uses of intrinsic biological fluorophores and also of fluorescent probes that have been designed to report on the presence or condition of biochemicals. In the Conclusion, several fluorescence approaches that may offer new capabilities in future biochemical studies are discussed. A fully comprehensive treatment of the diverse applications of fluorescence in biological studies is not possible in this article. For example, fluorescence studies of biological porphyrins—a vast field of spectroscopy—is mentioned in the most cursory fashion. Readers are encouraged to

refer to other articles as listed in Further reading section, for additional information, as well as to the sources in the Further reading list at the end of this article.

Overview of Measurement Formats

In Situ Measurements

In general, when information is sought regarding the spatial distribution of chemicals within cells or tissue, some variant of fluorescence microscopy is used—often in combination with transmission or Nomarski imaging. From an optical standpoint, fluorescence microscopy measurements either use a *wide-field* geometry, in which an entire field-of-view is illuminated simultaneously, or rely on raster scanning of a small resolution element to sequentially generate a fluorescence image. In the first approach, an arc lamp is commonly used as the excitation source and large-format images can be acquired at video rates using an array detector. In scanning fluorescence microscopy, a laser typically provides the excitation light, which is focused critically to diffraction spot sizes as small as $\sim 0.2\ \mu\text{m}$ using a high numerical aperture (NA) microscope objective. The sequential nature of image formation in scanning microscopy makes this procedure relatively slow. Although large format two-dimensional (2D) images typically require half a second or more to acquire, small 2D images or line scans can be produced much more rapidly. A fundamental advantage of the two scanning techniques most commonly used—confocal and multiphoton microscopies—is an ability to acquire 3D images of various biological specimens by scanning the laser focal spot in a given plane, then shifting the fine focus of the microscope to repeat the process in a new plane. In confocal microscopy, out-of-plane fluorescence is prevented from reaching a single-element detector by placing a small aperture in a plane conjugate to the focal spot; multiphoton microscopy achieves a similar degree

of axial resolution through an inherent 3D localization of the excitation focal volume.

Measurements with chemical separations

Though microscopy can be used to quantify simultaneously up to several chemical species by acquiring detailed spectroscopic information, when analysis of *many*, potentially unidentified, cellular components is desired, a separation procedure typically is used in combination with fluorescence detection. Commonly used techniques include high-pressure liquid chromatography (HPLC), capillary electrophoresis (CE) and related capillary chromatography techniques and gel electrophoresis. In HPLC and CE, trace analysis frequently is performed by labelling non-fluorescent components either pre- or post-separation using fluorogenic reagents. Capillary techniques frequently offer several advantages over HPLC, including faster and more efficient separations, lower sample volume requirements and alleviation of the need for high-pressure equipment. In DNA gel electrophoresis, fluorescent intercalating dyes can be used to stain oligonucleotide bands in gels after electrophoresis. For DNA sequencing in agarose gels, the Sanger method can be used to generate fluorescent fragments by labelling primers with fluorophores whose emission spectra encode a specific terminating dideoxy-ribo-nucleotide. Analysis of proteins using SDS-polyacrylamide slab gel electrophoresis or various capillary techniques can be accomplished by fluorescently labelling analytes before separation.

Cuvette, flow and 'chip' measurements

A large number of studies on isolated biochemical systems can be performed in cuvettes or deep-well slides. In particular, characterizations of macro-molecular structure are frequently conducted using thermostatted cells with capabilities for stopped-flow exchange of various solution modifiers (e.g. ligands, denaturants) on a millisecond timescale. In many cases, instruments used for such studies also can perform nanosecond or microsecond time-resolved measurements of emission intensity or polarization in addition to standard steady-state detection after polarization.

In many instances, it is desirable to rapidly count or isolate a subpopulation of cells exhibiting a particular chemical or characteristic. In flow cytometry, this property is linked to a corresponding difference in cellular fluorescence (e.g. by selectively labelling a relevant gene product), which provides a means for measuring relatively large numbers of cells in a flowing stream using automated instrumentation. Fluorescence-activated cell sorting (FACS) uses a flow cytometer in combination

with a shunting system to isolate cells exhibiting characteristic fluorescence.

The presence of various oligonucleotides, peptides and small molecules in solution can be analysed using solid state 'chip' based devices, in which receptor molecules (often antibodies or complementary oligonucleotides) immobilized on the chip surface bind the analyte(s) of interest. As a result of analyte binding, a characteristic fluorescence signal is generated from the receptor, analyte or some other interacting species. In ELISA (enzyme-linked immunosorbent assay), the binding of analyte is ultimately linked to the enzymatic production of a fluorescent solution-phase molecule.

Analyses Based on Intrinsic Biological Fluorescence

Ideally, all biological chemicals would carry highly specific spectroscopic signatures that define not only their identities but also every aspect of their physical states and environments, and they would yield optical signals intense enough to reveal the smallest changes relevant to a particular experiment. Biological analyses, of course, are not so straightforward and generally provide very limited information in the absence of exogenous 'probe' chemicals. Nevertheless, there are several classes of intrinsically fluorescent biological molecules, and a host of elegant spectroscopic techniques are used to investigate the properties of these species.

The aromatic amino acids – tryptophan (Trp), tyrosine (Tyr) and phenylalanine (Phe) – have strong deep-UV absorption bands ($\lambda_{\text{ex}} < 230$ nm) corresponding to $S_0 \rightarrow S_2$ transitions, but commonly are excited to the S_1 state in fluorescence studies ($\lambda_{\text{ex}} \approx 260\text{--}280$ nm) to minimize photoreaction and enhance fluorescence quantum yields (Φ_f). At these longer wavelengths, Trp has the largest molar extinction coefficient ($\epsilon_{\text{max}} \approx 5600$) and quantum yield ($\Phi_f \approx 0.2$) of the three amino acids; for Phe, the values of ϵ and Φ_f are so poor that this species is rarely useful in fluorescence studies. When subjected to UV irradiation, proteins with both Trp and Tyr (**Figure 1**) typically exhibit emission spectra whose shape is characteristic of Trp residues ($\lambda_{\text{max}} \approx 350$ nm) because of non-radiative energy transfer from Tyr to Trp.

Despite the fact that Trp and Tyr are not highly fluorescent and undergo intersystem crossing and myriad photoreactions with large quantum yields, these species can be useful probes of protein structure. Emission from both Trp and Tyr is quenched to different extents by a variety of intramolecular polar moieties (including carboxylic acids, amino groups and imidazole groups), bound cofactors (e.g. NAD^+), prosthetic groups (e.g. heme), and small molecules in solution, making determination of protein structural changes possible

Figure 1 Fluorescent amino acids.

through measurement of excited-state lifetimes or steady-state fluorescence intensities. Unlike Tyr, Trp fluorescence often is found to be higher in proteins than in free solution. In molecules containing multiple fluorescent residues, the overall modulation of fluorescence associated with protein conformational changes can be small due to an averaging of advantageous and deleterious quantum yield changes. For this reason, time-resolved measurements of multiexponential excited state decay times sometimes can provide information unavailable from steady-state intensity measurements.

The Stokes shift for Trp can also depend significantly on environment. When Trp is sequestered in the hydrophobic core of a protein, little or no reorientation of solvent takes place after excitation of the chromophore and emission is blue-shifted relative to a Trp residue on the exterior of a protein. Extreme examples include azurin, in which Trp appears to be completely isolated from H₂O ($\lambda_{\text{max}} < 310$ nm), and denatured parvalbumin, in which the Trp emission spectrum is essentially identical to free Trp. For proteins that contain Tyr but not Trp, the shapes of the emission spectra closely match free Tyr ($\lambda_{\text{max}} \approx 305$ nm), regardless of local chemical environment.

A number of macromolecular diffusion and conformational properties can be studied using fluorescence anisotropy, fluorescence correlation spectroscopy (FCS) and fluorescence recovery after photobleaching (FRAP). These techniques most commonly are applied to proteins labelled with highly fluorescent probes, but can exploit intrinsic fluorescence in some instances. In fluorescence anisotropy studies, polarized light is used to selectively excite molecules whose transition dipole moments are aligned with the electric field vector. Steady-state measurements of fluorescence anisotropy can be accomplished using a continuous excitation source; provided that anisotropy decays monoexponentially after excitation, information can be obtained on properties such as rotational diffusion times in membranes and the existence of ligand–host interactions. Time-resolved measurements, in which anisotropy is measured as a function of time following pulsed excitation, can provide more detailed information on phenomena such as anisotropic rotational diffusion and can be used to study complex

processes such as electron transfer in light-harvesting chlorophyll complexes. FCS is a steady-state technique for measuring the concentration and diffusion coefficient of a fluorescent molecule based on the magnitude of signal fluctuations as molecules diffuse through a finite probe volume. Diffusion coefficients can also be determined with FRAP, a technique in which fluorescent molecules within the probe volume are photo-bleached with a high-intensity pulse of light. After the bleaching event, the kinetics of fluorescence recovery (representing the diffusion of ‘fresh’ molecules into the probe volume) are monitored with low-intensity irradiation. Depending on the circumstances, FCS or FRAP can be useful for measuring the local viscosity of cellular or isolated biochemical environments, for monitoring ligand/host interactions and for determining changes in diffusion coefficients associated with macromolecular conformational changes.

Identification and measurement of UV fluorescent proteins in complex biological samples requires mixtures to be fractionated into individual components, often with CE or HPLC. CE with on-column UV fluorescence detection has been shown to be useful in measuring attomole quantities of protein in individual red blood cells. Peptide mapping can be accomplished using HPLC with post-column UV fluorescence detection by purifying individual proteins, then subjecting various fractions to proteolytic digests before separating the resulting peptide segments with chromatography.

Metabolic derivatives of Trp and Tyr also produce significant UV fluorescence. In some secretory cells, Trp is converted to the indolamine neurotransmitter, serotonin, which in turn can be processed into the pineal hormone, melatonin. Metabolic conversion of Tyr yields the catecholamines (dopamine, norepinephrine and epinephrine). Although the cellular concentration of transmitters is typically low, their concentrations within secretory granules can approach 1 molar. The fluorescence properties of these neurotransmitters are analogous to the parent amino acids, with indolamines exhibiting stronger emission and at longer excitation and emission wavelengths than the catecholamines.

Intrinsic UV fluorescence has been used to perform *in situ* measurements of serotonin. Loss of serotonin from astrocytes can be monitored using wide-field UV fluorescence microscopy after various chemical treatments. In addition, three-photon scanning fluorescence microscopy has been shown to be useful for tracking secretion of serotonin from granules in cultured cells in response to cross-linking of cell surface IgE receptors. Fluorescence from indolamines and catecholamines separated with CE has provided a means to measure these species in the low- to mid-attomole range.

In some instances, protein fluorescence does not derive directly from the aromatic amino acids. Two such proteins

native to the jellyfish genus *Aequorea* – *aequorin* and the *green fluorescent protein* (GFP) – have been particularly useful tools in biochemical studies. Aequorin emits light ($\lambda_{\text{max}} \approx 470 \text{ nm}$) from the bound luminophore coelenterazine as the result of a Ca^{2+} -promoted oxidation reaction and hence has been useful as an intracellular Ca^{2+} probe both through microinjection and recombinant gene expression. The discovery and cloning of GFP has attracted much attention in part because of its utility as a reporter for various gene products when incorporated into fusion proteins. In GFP, the chromophoric unit has been identified as an imidazolone anion formed by cyclization and oxidation of tripeptide sequence (-Ser-Tyr-Gly-); fluorescence of this species is characterized by excitation maxima at ~ 400 and $\sim 475 \text{ nm}$ and peak emission at $\sim 510 \text{ nm}$. The fluorescence from GFP is intense enough to detect individual molecules of this species immobilized in aqueous gels. Both aequorin and GFP can be genetically targeted to accumulate in specific organelles to measure localized properties, such as $[\text{Ca}^{2+}]$ and protein diffusion coefficients in mitochondria.

A variety of protein cofactors have significant intrinsic fluorescence, including the reduced nicotinamide nucleotides (NADH and NADPH) and the oxidized flavins (Figure 2). The nicotinamides are excited in the near-UV and emit maximally at $\sim 470 \text{ nm}$; flavins exhibit both near-UV and visible excitation maxima, and have a peak emission at $\sim 515 \text{ nm}$. In both groups of cofactors, the adenine group partially quenches fluorescence through collisions; in flavins, adenine also can quench fluorescence by forming an intramolecular complex with the fluorescent ring system. The significance of adenine quenching is underscored by the fact that flavin mononucleotide (FMN), a highly fluorescent cofactor that lacks adenine, has a fluorescence quantum yield 10-fold greater than that of flavin adenine dinucleotide (FAD). Flavins that are covalently or non-covalently bound to proteins display widely varying differences in fluorescence quantum yields, although flavoproteins often are relatively non-fluorescent. In contrast, NADH bound to proteins sometimes has substantially greater fluorescence than free NADH because of a decreased ability of adenine to quench the nicotinamide group. In dehydrogenases, for example, crystallographic studies indicate that nicotinamide cofactors are bound in an extended fashion, with the adenine and nicotinamide groups bound to different pairs of β -sheets. Moreover, conformational changes in lactate dehydrogenase induced by effector molecules can be monitored as changes in NADH fluorescence. As a rule, the redox cofactors – like the fluorescent amino acids – have spectroscopic properties that are sensitive to environment and can be used to probe conformational changes in proteins.

NADH and oxidized flavin (flavoprotein) fluorescence can be used as an indicator of the redox states of cells

Figure 2 Three fluorescent cofactors.

challenged with a variety of chemical effectors and has been used to correlate the oxidative status of cells *in situ* and *in vivo* to functions such as electrical activity in brain tissue. The fluorescence of NADH also has been used to characterize the *in vitro* activity of individual lactate dehydrogenase molecules, which reduce the non-fluorescent NAD^+ during oxidative production of pyruvate. This general strategy, in which single-enzyme molecules are characterized through the generation of a fluorescent product, can also be applied to reactions using engineered (non-biological) fluorogenic substrates.

Most nucleic acids have poor fluorescence properties because of extremely short excited state lifetimes and are most often studied using non-biological intercalating or groove-binding dyes. One notable exception is the *Y base*, which has been used as an indicator of tRNA folding induced by divalent cation binding. In addition, some nucleotides exhibit moderate fluorescence under highly acidic conditions and can be measured in attomole to femtomole amounts using CE.

Analyses Using Non-biological Probes

Although fluorimetric analysis of biological systems is experimentally simpler and less disruptive to inherent chemical properties when the use of synthetic fluorescent

molecules can be avoided, in many instances the intrinsic properties of biological chemicals do not provide sufficient means for characterizing or quantifying desired properties. In the case of protein analysis, for example, many species lack Trp or Tyr residues altogether; in protein molecules that do contain these amino acids, the fluorescence characteristics may be inadequate to yield the needed information.

Numerous probes have been developed for investigating biological molecules *in vitro* and in living cells, with greatly differing strategies for uncovering desired information. No common photophysical or photochemical characteristics can be ascribed to this entire assortment of non-biological fluorophores. Many probes have been engineered to have very large absorption cross sections and fluorescence quantum yields and to be resistant to photoreaction. The probes based on laser dyes such as fluorescein ($\epsilon_{\text{max}} > 50\,000$; $\Phi_f > 0.9$) or one of the rhodamines are good examples of this class of molecules and often are incorporated in a number of the calcium probes, fluorescent antibodies (see in subsequent paragraph) and reagents used to label proteins for conformational studies involving fluorescence anisotropy, FCS and FRAP. In addition, by conjugating two spectroscopically distinct probes to different sites on a molecule, Förster energy transfer between the fluorophores can be used to measure intramolecular distances. Despite the advantages of these highly fluorescent molecules, probes having *less* optimal fluorescence properties are deliberately selected for some applications—often as a compromise to achieve a greater *change* in optical characteristics under different chemical environments or to avoid toxicity to living cells. For example, a dye whose fluorescence properties depend sensitively on the polarity and rigidity of its local environment may be more useful in many instances than a rhodamine for characterizing protein conformation. One such compound is NBD chloride, an amine-reactive reagent whose product has a markedly greater Φ_f value when occupying a hydrophobic site.

Reactive fluorogenic reagents (e.g. NBD chloride, fluorescamine and CBQCA) are essentially non-fluorescent until they react with analyte molecules, and are commonly used to tag biological species that share a particular reactive group (e.g. a thiol or amine). This low-specificity labelling approach is extremely useful for identification and measurement of many low-concentration species in a mixture when some means exist for fractionating the multiple components (e.g. HPLC). Because of the low level of reagent fluorescence, a large excess of these species typically can be present in the reaction mixture without interfering with analysis.

When characterizing samples containing many biomolecules, a probe that reacts with a particular chemical moiety sometimes does not provide adequate specificity,

even when used with a highly efficient separation procedure. Analysis of the protein distribution in cellular specimens is perhaps the quintessential high-specificity requirement. Because of the value of such measurements in characterizing cellular composition, immunohistochemistry is one of the most ubiquitous biological applications of fluorescence. In routine determinations of gene products, cultured cellular samples or sectioned tissue are chemically fixed and subjected to sequential application of primary and secondary antibodies, followed by imaging with fluorescence microscopy. Primary antibodies can be raised against a tremendous diversity of cellular species, ranging from membrane proteins to small diffusible species such as neurotransmitters. Several species can be analysed in a single specimen by covalently attaching dyes with different excitation/emission spectra to different secondary antibodies. Most commonly, fixed and labelled samples are analysed using either wide-field or confocal laser scanning microscopy. When one seeks to analyse a solution sample for the presence of a known antigen, ELISA can be used. In one format, an immobilized antibody binds the antigen, removing it from solution. A second antibody which is conjugated to an enzyme capable of converting a non-fluorescent substrate into a fluorescent product is then applied that binds to the immobilized antigen. After a washing step, the enzymatic reaction is initiated. In this way, large signal amplifications provide extremely sensitive assays for analytes such as hormones and drug metabolites. Although immunological techniques can be useful for measuring analyte concentrations, uncertainties in cross-reactivity and matrix effects on the antibody-antigen conjugation efficiency often limit this approach to semiquantitative determinations.

Diffusible cytosolic species (e.g. second messengers) can be measured in living cells using highly specific fluorescent probes. The calcium-sensitive dyes, a broad class of molecules whose excitation or emission properties are dependent on chelation of Ca^{2+} , are ubiquitous in cellular biology studies. For such compounds, it is important that affinity for Ca^{2+} is much greater than for other cationic species that may be present in the cytosol at much higher concentrations (e.g. Mg^{2+}). In general, cytosolic free Ca^{2+} concentrations vary over the approximate range 100 to 1000 nM, although much higher levels are sometimes reached transiently. Common examples of Ca^{2+} -sensitive dyes include fluo-3 (100-fold intensity increase when bound to Ca^{2+}), fura-2 (excitation λ_{max} changes when bound to Ca^{2+}) and indo-1 (emission λ_{max} changes when bound to Ca^{2+}) (**Figure 3**). For these species, the Ca^{2+} dissociation constant has been designed to approximately match free cytosolic levels, thus maximizing the modulation in fluorescence for a given change in $[\text{Ca}^{2+}]$. Like Trp, indo-1 has an indole-based chromophore, but in this case the π -system is

Figure 3 Two common calcium probes.

further delocalized to electronically interact with carboxylate groups responsible for Ca^{2+} chelation. In many instances, fura-2 and indo-1 may offer advantages over fluo-3, as ratiometric measurements of excitation or emission intensities at two different wavelengths can help avoid errors associated with uncertainties in intracellular dye concentrations. Calcium probes have played an invaluable role in identifying a range of cytosolic phenomena, such as $[\text{Ca}^{2+}]$ spiking after hormone binding to cell surface receptors and Ca^{2+} waves in oocytes following a fertilization event. Probes exist for other important cytosolic effectors, such as cyclic AMP (cAMP), which is monitored by the level of Förster energy transfer between fluorescein and rhodamine attached to a cAMP-binding enzyme.

Although it is possible to microinject dyes for probing cytosolic milieus through patch or intracellular pipettes, it is more common to incubate many cultured cells in a medium containing low molecular mass dyes in an esterified form (e.g. acetoxymethyl or 'AM', ester). This parent species is hydrophobic and thus can diffuse freely through cell membranes. Once the compound is localized to the cytosol, non-specific esterases hydrolyse the

hydrophobic group, generating a charged form of the probe that can no longer diffuse through the membrane. Large numbers of cells can also be loaded rapidly using electroporation.

Structures in living cells often can be characterized using probes with specificity for *classes* of molecules rather than for particular target analytes. Hydrophobic or amphipathic dyes, for example, can be used to gauge cell membrane fluidity and diffusion, as well as exocytosis of secretory vesicles and subsequent membrane recycling. Examples of this class of dyes are 8-anilinoanthralene sulfonate (ANS), which displays significant fluorescence only when bound to membranes (or protected hydrophobic regions of proteins), and FM-143, a compound used extensively to study regulated secretion from neurons. Some membrane dyes have been engineered (or serendipitously found) to alter their fluorescence properties based on the electric field across the phospholipid bilayer of cell or organelle membranes. Typically, such potentiometric dyes either respond with fast kinetics to electric field changes but display small modulations in fluorescence (e.g. the styrylpyridinium probes) or undergo large fluorescence changes but only very slowly. Because large, rapid changes in fluorescence generally are not obtained with existing probes, it is difficult to perform voltage measurements on individual neurons and other excitable cells.

Other fluorogenic dyes, such as DAPI, ethidium bromide and the cyanine dyes, bind to DNA or RNA and undergo changes in fluorescence intensity of up to 1000-fold. Depending on the probe, these compounds can be used to image fixed cells or track mitotic events. Combinations of probes with different specificities for single-stranded, double-stranded and ribosomal RNA have been used to characterize the quantity and conformation of nucleic acids throughout the cell cycle.

Conclusion

In the 50 years since the intrinsic fluorescence of amino acids was first characterized, fluorescence spectroscopy has developed into one of the most versatile and powerful tools for investigating biochemical systems. In addition to the enormous range of applications that now exist, a variety of emerging analysis strategies provide evidence of a continued phase of rapid growth for fluorescence applications. Developments in instrumentation – laser sources, optics, and detectors – have made possible the characterization of individual enzyme molecules and highly fluorescent proteins such as GFP and β -phycoerythrin, a light-harvesting protein. Solid-state femtosecond sources recently have made it feasible to generate multiphoton-excited fluorescence of biological molecules in solution using relatively low integrated

irradiation and have provided reproducibility necessary for experiments involving living specimens.

Various technologies that rely on fluorescence for high-sensitivity analysis have been made possible through advances in microfabrication and robotics. Examples include chip-based microarray sensors for detecting a multitude of ligands simultaneously, such as for gene expression profiling, and chips containing arrays of microscopic electrophoresis channels for performing high-throughput, rapid separations of DNA fragments.

Other fluorescence techniques exploit the evanescent or near-field, properties of light to excite fluorescence in highly restricted regions of space, thereby improving measurement sensitivity or the spatial resolution of fluorescence imaging. Near-field scanning optical microscopy (NSOM) can image structures smaller than the diffraction limit of light using fluorescence generated by an evanescent field that escapes from the aperture at the end of a drawn, metallized fibre. The resolution obtained with this approach is determined by the dimensions of the aperture, which is usually limited by losses in throughput as the fibre tip diameter is reduced. Thus far, only a few biological applications of this powerful technique have been reported.

Probably the most heavily used application of fluorescence today is in the proliferation of microchip arrays for gene expression profiling to evaluate changes caused by disease or drug therapy. However, new developments in the chemistry of fluorescent probes undoubtedly will open new applications for fluorescence in biochemistry. A growing number of companies and academic researchers are devising new biological probes and in some cases are using non-traditional strategies – such as combinatorial chemistry – to generate hosts with high specificity and large binding constants for desired ligands. Genetic manipulation of cultured cells offers particularly exciting opportunities for *in situ* biochemical measurements. Technology now exists for using an enzyme as a reporter for neurotransmitter-activated transcription in individual mammalian cells, with sensitivities capable of measuring fewer than 50 gene product molecules. In an initial demonstration of this strategy, large amplifications of gene product expression were obtained by localizing an engineered substrate to the cytosol whose fluorescence properties change when it is degraded by the reporter enzyme. Through the judicious use of molecular and cellular biology, chemistry and fluorescence spectroscopy, eventually it may be feasible to track the production and breakdown of individual molecules in living cells.

Until the late 1960s, Raman spectroscopy was largely restricted to small inorganic and organic molecules. Concomitant to the substantial improvement of excitation sources and detection systems beginning in the early 1970s, biological molecules, which in most cases are weak Raman scatterers, became more and more accessible to this technique. Now, Raman spectroscopy has been developed to become a versatile tool for studying biological systems on various levels of complexity, that is ranging from small amino acids to biopolymers and even to living cells.

Raman spectra – like IR spectra – include detailed information about the molecular structure and, hence, may provide a key for elucidating structure–function relationships. Unfortunately, the ability to extract structural data from the spectra is much less advanced than, for example, in NMR spectroscopy, since a sound vibrational analysis based on normal mode calculations is not straightforward. Empirical force fields only provide meaningful results in the case of small and symmetric molecules for which a large set of isotopomers are available. Alternatively, quantum chemical methods can be employed to calculate the force constants. Despite the recent progress in hardware, and software developments, this approach is still restricted to prosthetic groups and building blocks of biopolymers. Thus, in most cases, the interpretation of the Raman spectra of biomolecules is based on empirical relationships derived from comparative studies of model compounds.

The large number of normal modes of biomolecules is also associated with an experimental difficulty inasmuch as individual Raman-active modes may be closely spaced so that the observed peaks include several unresolved bands. This is particularly true for modes which originate from chemically identical building blocks of the biopolymers, such as the amide vibrations of proteins. In these cases, however, the analysis of these bands provides valuable information about the structure of the ensemble of these building blocks, for example the secondary structure of proteins.

The selectivity of Raman spectroscopy can be substantially increased by the choice of an appropriate excitation wavelength. When the excitation energy approaches that of an electronic transition of a molecule, exclusively the Raman intensities of the modes originating from this chromophore are enhanced by several

orders of magnitude (resonance Raman, RR). In this way, it is possible to probe the vibrational band pattern of this specific part of the macromolecule regardless of the size of the remaining optically transparent matrix.

Specific Experimental Considerations

Under non-resonant conditions, quantum yields for the Raman effect are in the order of 10^{-9} , implying that sample concentrations in the millimolar range are required for obtaining Raman spectra of satisfactory quality. Resonance enhancement substantially improves the sensitivity, but even RR intensities are too weak to obtain spectra of samples which exhibit a strong fluorescence or which contain strongly fluorescent impurities. In those cases, Fourier-transform near-infrared Raman spectroscopy may be a useful alternative approach.

Possible thermal denaturation or photochemical processes which may be induced by laser irradiation may impose serious constraints on Raman (RR) spectroscopic experiments of biomolecules. Such effects can be reduced by using appropriate sample arrangements such as flowing or rotating devices, or by lowering the temperature.

In any case, the photon flux through a volume element of a sample should be kept as small as possible to ensure the integrity of the biomolecule during the Raman experiment. These requirements are best fulfilled using continuous wave lasers as excitation sources. A second parameter which is essential for measuring the spectra of sensitive biomaterials is a short duration of the Raman experiment. Scanning monochromatic detection systems (photon counting devices) may require several hours to obtain Raman spectra of sufficient quality. Polychromatic detection systems can strongly reduce the total signal accumulation time and, in the case of CCD detectors, yield a spectral resolution and signal-to-noise ratio comparable to scanning systems.

Structure of Biomolecules

Raman spectroscopic studies which are directed to gain information about the structure of biomolecules are generally performed in the stationary mode. Such

experiments have been carried out with all kinds of biopolymers and their building blocks. However, up to now, the level of spectral analysis and interpretation is such that reliable structural information can be extracted from the spectra only for proteins, nucleic acids and membranes.

Proteins and Amino Acids

Non-resonant Raman spectra of proteins display bands originating from the protein backbone, that is the amide modes and the amino acid side chains, in particular, the aromatic amino acids tryptophan (Trp), tyrosine (Tyr) and phenylalanine (Phe). The strongest amide band in the non-resonant Raman spectra originates from the amide I mode which is essentially a pure C=O stretching of the peptide bond. Its frequency depends on the type of hydrogen bonding and dipole–dipole interactions associated with the peptide bond. As these interactions are different for the various elements of secondary structure of proteins, systematic Raman and IR spectroscopic studies of peptides and proteins with known three-dimensional structure allow the determination of amide I frequencies which are characteristic not only for the main secondary structure elements α -helix (1657 cm^{-1}) and β -sheet (1626 and 1635 cm^{-1}) but also for turns (1666 cm^{-1}) and β -sheet/turns (1679 cm^{-1}). For irregular or random coil peptide bonds, the amide I is found at 1644 cm^{-1} . These findings constitute the basis for the secondary structure determination of proteins and peptides of unknown structure. In the most general way, the measured amide I envelope is fitted by a set of these bands with constant frequencies and half widths. The relative intensities, which are the only adjustable parameters, represent a measure for the relative contributions of the various secondary structure elements. This approach is also frequently used in IR spectroscopy which offers the advantage of a better signal-to-noise ratio but is restricted to measurements in D_2O due to the strong absorption of water. With an increased set of reference proteins, the method has gained a considerable accuracy, which can well compete with CD measurements.

Complementary information about the secondary structure can be obtained by using RR spectroscopy. Upon excitation in resonance with the $\pi \rightarrow \pi^*$ transitions of the peptide bonds at $\sim 190\text{ nm}$, the amide modes II, III and II', which include the C–N stretching vibrations, are preferentially enhanced so that they appear with substantially higher intensity than the amide I mode (C=O stretching), which in turn gains intensity only via a higher lying electronic transition at $\sim 160\text{ nm}$. Like the amide I mode, the amide modes II, III and II' are at different frequencies in the various structural elements. More important for secondary structure determination,

however, are the RR intensities of these modes. The qualitatively different dipole–dipole interactions in α -helical and β -sheet structures lead to a respective decrease (hypochromic effect) and increase (hyperchromic effect) of the oscillator strength, which in turn affects the Raman cross-sections of these amide modes. Thus, it was possible to derive (linear) relations between the RR intensities of these modes (determined relative to an internal standard) and the secondary structure. Owing to the high energy of the deep UV laser pulses required as the excitation source, special attention has to be paid to avoiding photodegradation processes of the biomolecule.

Such effects are also a restriction on probing the aromatic amino acid side chains of proteins using excitation lines between 200 and 240 nm. Under these conditions, several ring vibrational modes are selectively enhanced via the L_a (Phe, Tyr) and $B_{a,b}$ transitions (Trp). The frequencies and relative intensities of these modes can be used to study the local environment of these amino acids, that is to obtain information about this specific part of the tertiary structure. In particular, the modes of Tyr and Trp may provide more detailed information about the local protein structure. The *p*-hydroxy substituent of Tyr is generally involved in hydrogen bonding interactions with hydrogen bond acceptors or donors. These interactions are sensitively reflected by the modes ν_{7a} , $\nu_{7a'}$ and ν_{9a} since their frequencies show linear relations with the solvent donor number. Monitoring these modes in proteins allows conclusions about the kind and the strength of hydrogen bonding interactions of Tyr. In the extreme case, when Tyr is deprotonated, the entire vibrational band pattern drastically changes and, due to the redshift of the electronic transition, the resonance enhancement is altered. Also Trp can undergo hydrogen bonding interactions via the indole N–H group. In that case, a band at $\sim 880\text{ cm}^{-1}$ (ν_{10a} , W17) is an appropriate marker in the RR spectra of proteins. The second important spectral marker of Trp, a Fermi doublet at $\sim 1345\text{ cm}^{-1}$, exhibits a moderate resonance enhancement and can only be identified in the spectra of relatively small proteins. This band is an indicator for the hydrophobicity of the local environment of the indole ring. On the basis of systematic studies of Trp and model compounds, an empirical relationship has been derived between the torsional angle of the $\text{C}_2\text{--C}_3\text{--C}_\beta\text{--C}_\alpha$ entity and the frequency of the band at $\sim 1550\text{ cm}^{-1}$ (W3). This marker band, however, does not appear to be applicable for analysing the Trp structure in proteins inasmuch as it appears in a spectrally crowded region.

Although a priori the size of the protein is not a limitation for UV RR spectroscopic analysis of aromatic amino acids, increasing numbers of Phe, Tyr and Trp residues strongly complicate the interpretation of the

spectra. Nevertheless, working with high-quality spectra it is possible to probe subtle structural changes of a single amino acid even in relatively large proteins as demonstrated in the studies on haemoglobin by Spiro and co-workers. This protein consists of two ($\alpha\beta$) dimers, each of them including 15 Phe, 6 Tyr and 3 Trp residues. It had been assumed that the T→R transition of haemoglobin was associated with a change of hydrogen bonding interactions of one Tyr (out of 12), which in fact could be confirmed by UV RR (difference) spectra.

The application of Raman spectroscopy for probing amino acid side-chain structures in proteins is not restricted to excitation in the deep UV. Some ring vibrations of the aromatic amino acid side chains can also be identified in the nonresonance Raman spectra. These are, for instance, the Fermi doublet of Trp at $\sim 1345\text{ cm}^{-1}$ and a band pair of Tyr at 850 and 830 cm^{-1} , assigned to the fundamental mode ν_1 and the overtone $2\nu_{16a}$, which together form a Fermi doublet as well. This doublet, which is only weakly resonance enhanced upon UV excitation, appears with considerable intensity under non-resonance conditions and is known to be a sensitive marker for hydrogen bonding interactions as derived from systematic studies on model compounds. In fact, the intensity distribution of this doublet can be used to monitor changes of hydrogen bonding interactions of Tyr in proteins.

Among the aliphatic amino acid side chains, cysteine (Cys) and methionine (Met) give rise to particular strong Raman bands which appear in less diagnostic spectral regions. The C–S stretching is found between 620 and 750 cm^{-1} depending on the conformation of the side chain, for example *trans* or *gauche* conformation of Met. In addition, the C–S stretching vibrations of disulfide bridges, which constitute an important stabilizing factor for the tertiary structure of proteins, are observed at 630 – 650 , 700 and 720 cm^{-1} when the *trans* substituent X of the $\text{X-C}_\alpha\text{-C}_\beta\text{-S-S}$ entity is a hydrogen, nitrogen and carbon atom, respectively. However, the most characteristic feature of disulfide bridges is the S–S stretching (500 – 525 cm^{-1}). There is a large body of experimental data for proteins and model compounds and evidence has been provided for a linear correlation between the frequency and the C–S–S–C dihedral angle.

Chromoproteins

Chromoproteins are characterized by an electronic absorption band in the near-UV, visible or near-IR spectral range. These bands may arise from $\pi \rightarrow \pi^*$ transitions of prosthetic groups or from charge-transfer transitions of specifically bound transition metal ions. Thus, chromoproteins which may serve as electron transferring proteins, enzymes or photoreceptors are particularly

attractive systems to be studied by RR spectroscopy since an appropriate choice of the excitation wavelength readily leads to a selective enhancement of the Raman bands of the chromophoric site. Moreover, these chromophores generally constitute the active sites of these biomolecules so that RR spectroscopic studies are of utmost importance for elucidating structure–function relationships.

Photoreceptors may use light either for energy conversion (photosynthetic pigments, bacterial rhodopsins) or as a source of information to trigger a physiological response (rhodopsins, phytochromes). Typical chromophores are retinal Schiff bases which are covalently attached to the apoprotein ((bacterial) rhodopsins) and cyclic or linear tetrapyrroles (photosynthetic pigments, phytochromes). In the case of (bacterial) rhodopsins and phytochromes, light absorption initiates a photochemical reaction which is followed by a series of thermal relaxation processes. Thus, RR spectroscopic studies of these biomolecules encounter the difficulty that the exciting laser beam induces the reaction sequence. To avoid accumulation of various intermediate states, low temperature spectroscopy is frequently employed so that thermally activated reaction steps can be blocked. Alternatively, time-resolved RR spectroscopy may be an appropriate approach (e.g. bacteriorhodopsin) which, in addition, provides information about the chromophore–protein dynamics.

Primary interest of RR spectroscopic investigations of the visual pigment rhodopsin was directed to the analysis of the photochemical reaction. Single-beam experiments carried out at 77 K yielded a photostationary equilibrium of the parent state and the primary photoproduct. Using an additional laser beam of a wavelength in resonance with the electronic transition of the product, it was possible to shift the equilibrium largely to the parent state. Thus, subtracting the dual-beam- from the single-beam-excited spectrum yielded a pure spectrum of the parent state. The interpretation of these spectra was greatly facilitated by the large body of experimental data of retinal model compounds including a variety of isotopomers as well as of the detailed investigations of bacteriorhodopsin (see the following text). Moreover, normal mode analyses based on empirical force field calculations support a reliable vibrational assignment allowing for the determination of the configurational and conformational state of the retinal chromophore. In this way, it could be shown that the primary photoprocess of the parent state in which the retinal is in the 11-*cis* configuration leads to a distorted all-*trans* configuration. Unusually strong intensities of the C–H out-of-plane vibrations of the retinal chain were taken as a measure of the torsion of the C–C single bonds of the chain. These intensities decrease in the intermediates formed during the subsequent thermal reactions indicating a relaxation

of the chromophore geometry and the immediate protein environment. In the final step, the Schiff base, that is the covalent linkage to the apoprotein, was deprotonated as indicated by the shift of the C–N stretching vibration and its insensitivity towards H/D exchange. Furthermore, analysis of the RR spectra in terms of retinal–protein interactions contributed essentially to the understanding of colour regulation mechanism in vision.

In addition to its photolability, the plant photoreceptor phytochrome, whose chromophore is a linear tetrapyrrole, exhibits a relatively strong fluorescence which severely hinders RR spectroscopic studies under rigorous resonance conditions. Thus, Mathies and co-workers employed shifted-excitation Raman difference spectroscopy in which two spectra, measured with excitation lines separated by 10 cm^{-1} , were subtracted from each other. In this way, the fluorescence background was removed yielding only difference signals which were used to calculate the absolute RR spectrum. Similar spectra were obtained by an alternative approach using Fourier-transform Raman spectroscopy at low temperature (77 K). In that case, the excitation line in the near-infrared is shifted from the electronic transition of the chromophore to circumvent fluorescence (and unwanted photochemical processes) but yields a sufficient pre-resonance enhancement so that the spectra are dominated by the RR bands of the tetrapyrrole. In addition to the spectra of the parent states, those of the intermediates of the photoinduced reaction cycle were obtained by controlled illumination and increase of the temperature. As shown in **Figure 1**, the spectra of the various states of phytochrome (of the $P_r \rightarrow P_{fr}$ transformation) reveal substantial differences reflecting the changes of the chromophore configuration, conformation and interactions with the surrounding protein. In contrast to retinal proteins, however, analysis of the vibrational spectra of linear tetrapyrroles is much less advanced so that up to now only a little structural information can be extracted from the spectra. Progress in spectral interpretation can be expected by extending the studies to recombinant phytochromes including chemically modified and isotopically labelled chromophores as well as by normal analyses based on quantum chemical force field calculations.

For RR spectroscopic studies of photosynthetic pigments, the intrinsic chromophore fluorescence is again an annoyance. In addition to the techniques employed in phytochrome studies, chlorophyll-containing biomolecules allow excitation in resonance with the second (non-fluorescing) electronically excited state ($\sim 350\text{--}400\text{ nm}$). In the RR spectra of chlorophylls several bands have been identified which are known to be sensitive markers for the coordination state of the central Mg ion. These bands as well as those originating from the C=O stretchings of the formyl and keto substituents provide information about chlorophyll–chlorophyll and chlorophyll–protein

interactions. This information was particularly helpful for elucidating the structural motifs of the chromophore assemblies in light-harvesting pigments. RR spectroscopic studies of genetically engineered protein variants of reaction centres have contributed to the understanding of those parameters controlling redox potentials and electron-transfer processes.

In contrast to photoreceptors, haem proteins are readily accessible for RR spectroscopy inasmuch as they exhibit strong electronic transitions in the visible and near UV. Moreover, they are photostable and do not reveal any interfering fluorescence. There are numerous review articles on the RR spectroscopic results obtained for various representatives of this versatile class of chromoproteins which includes redox enzymes, electron-transferring proteins and oxygen transport proteins. Interpretation of the RR spectra is backed by extensive empirical material accumulated from studies on metalloporphyrins in which spectral and structural properties were correlated. Thus, the RR spectra of haem proteins can be interpreted in terms of the kind of the porphyrin, the coordination sphere of the central iron, distortions of the haem geometry, and haem–protein interactions via the porphyrin substituents and the axial ligands. As an example, **Figure 2** shows the RR spectra of cytochrome c_{552} in the oxidized and reduced state, displaying the RR bands in the region of those marker bands whose frequencies are characteristic for the oxidation, spin and coordination state of the haem iron.

In addition to the investigations which aim to characterize the structure of the haem pocket, many studies were directed to solve specific problems related to the function of the haem protein under consideration. Detailed studies were carried out on the cytochrome c –cytochrome c oxidase redox couple to understand the interprotein electron transfer mechanism. Specific emphasis was laid on the analysis of the protein complexes formed prior to the electron transfer to assess the effect of protein–protein interaction on the structure of the individual haem sites. In these experiments, dual channel Raman spectroscopy, which permits the quasi-simultaneous measurement of two spectra, is particularly useful for the detection of subtle spectral changes. In this way, RR spectroscopy provided evidence for a considerable conformational flexibility of both proteins, which may be of functional relevance. Many studies of haem enzymes (e.g. cytochrome P-450) were directed to elucidate substrate-binding and substrate-specificity on a molecular level.

An interesting approach for probing molecular details of the haem pocket is the use of carbon monoxide which may occupy a vacant coordination site of the haem. The vibrations of the Fe–CO entity can be analysed in terms of the orientation of the CO ligand with respect to the haem plane, which, in turn, depends on the molecular

Figure 1 Fourier-transform RR spectra (1064 nm) of various states of phytochrome trapped at low temperature. (a) P_r ; (b) Lumi-R; (c) Meta-R_a; (d) Meta-R_e; (e) P_{fr} .

Figure 2 RR spectra (413 nm) of cytochrome c_{552} of *Thermus thermophilus* in the reduced state (a) and the oxidized state (b).

interactions in the haem pocket. Such studies are particularly relevant for oxygen-binding proteins inasmuch as CO is an appropriate analogue for molecular oxygen.

Whereas those chromoproteins discussed so far include prosthetic groups with delocalized π -electron systems, the chromophoric site in metalloproteins is constituted by a transition metal ion coordinated by various amino acid side chains. Excitation in resonance with charge-transfer transitions leads to a predominant enhancement of the metal-ligand vibrations and, to some extent, of internal ligand vibrations. Thus, the corresponding RR spectra are less complex although the interpretation is not necessarily unambiguous and straightforward in each case. Among these proteins, iron-sulfur proteins, blue-copper proteins and non-haem iron proteins have been studied extensively by RR spectroscopy.

Iron-sulfur proteins reveal a characteristic vibrational band pattern in the low frequency region which, in many cases, can be used to identify the type of the iron-sulfur cluster based on a comparison with the spectra of model compounds and related proteins of known structure. However, such studies are restricted to the oxidized form since the reduced complexes do not exhibit a charge-transfer transition in the visible region. This is also true for the blue-copper proteins for which the RR spectrum is dominated by modes, including the Cu-S(Cys) stretching coordinate as well as internal modes of the Cys ligand. A substantial improvement of the understanding of these spectra was achieved by using protein variants with isotopically labelled amino acids.

The key issue for RR spectroscopists dealing with non-haem iron proteins is to determine the geometry of the oxygen-bridged binuclear complexes as well as to identify the nature of the ligands. In these studies, the RR spectra of ^{18}O -labelled samples significantly support the interpretation.

Nucleic Acids

Raman bands of nucleic acids originate from in-plane vibrations of the nucleic acid bases (adenine, guanine, cytosine, thymine and uracil) and from the furanose-phosphate backbone. In general, Raman spectra of DNA or RNA reveal structural information about base stacking and interbase hydrogen bonding interactions. Whereas base stacking is reflected solely by intensity variations of purine and pyrimidine bands, changes of interbase hydrogen interactions, for instance, due to helix formation or conformational transitions of the helix, are indicated by both intensity changes and frequency shifts. Raman spectroscopy offers the possibility to determine the conformation of the nucleic acid inasmuch as there are marker bands indicative for the A-, B- and Z-forms of DNA. The most characteristic marker bands originate from the backbone since the various helical structures differ with respect to the sugar-phosphate conformation. The basis of the comparison of various DNAs of known crystal structure, it was found that the phosphodiester symmetric stretching vibration is at $811 \pm 3 \text{ cm}^{-1}$ in A-DNA whereas it is upshifted to $835 \pm 5 \text{ cm}^{-1}$ in the B-form. Furthermore, some ring vibrations of nucleic acid bases, particularly of guanine and cytosine, also serve to distinguish between the various DNA structures (Table 1). For quantitative analysis of the DNA structure, the relative intensities of these specific marker bands can be used to assess the percentage of A-, B- and Z-conformations using the conformation-insensitive band at 1100 cm^{-1} (symmetric stretching of the PO_2 group) as a reference.

In general, structural changes of DNA in biological processes, such as transcription, replication or DNA

Table 1 Conformation-sensitive non-resonant Raman bands of nucleic acids

Frequency (cm^{-1})	Description
805–815	phosphodiester symmetric stretching: C-3'-endo conformation (A-DNA)
835 (weak)	phosphodiester symmetric stretching: C-2'-endo conformation (B-DNA)
870–880	phosphodiester symmetric stretching: C-DNA
682	guanine ring breathing: C-2'-endo-anti (B-DNA)
665	guanine ring breathing: C-3' endo-anti (A-DNA)
625	guanine ring breathing: C-3' endo-syn (Z-DNA)
1260 (weak)	cytosine band: B-DNA
1265 (strong)	cytosine band: Z-DNA
1318 (moderate)	guanine band: B-DNA
1318 (very strong)	cytosine band: Z-DNA
1334 (moderate)	guanine band: B-DNA
1355 (moderate)	guanine band: Z-DNA
1362 (moderate)	guanine band: B-DNA
1418 (weak)	guanine band: Z-DNA
1420 (moderate)	guanine band: B-DNA
1426 (weak)	guanine band: Z-DNA

packaging, are not global but are restricted only to a few nucleotides along the chain. Such changes can induce local melting of the secondary structure, reorientations and disruptions of the base stacking. Melting of RNA and DNA double helices always leads to the disappearance of the 814 and 835 cm^{-1} bands, indicating a decrease in furanose conformational order and an increase of the backbone chain flexibility. Precise thermal melting profiles of both RNA and DNA double helical complexes have been determined based on the intensity variations of these bands. A careful analysis of the Raman spectra of nucleic acids allows the detection of subtle alterations of the helical organization. This has been demonstrated in studies of DNA packaging, which involves formation of DNA-protein complexes with a series of histone and non-histone proteins. A backbone conformation of the B-type family was consistently observed for the nucleosome DNA complexes irrespective of the histone and nonhistone content. Furthermore, complex formation is reflected by the intensity decrease of the adenine and guanine ring modes at 1490 and 1580 cm^{-1} , respectively. Whereas the intensity attenuation of the 1580 cm^{-1} band was attributed to the binding of histone proteins in the small grooves of double helical B-form DNA, the spectral changes of the 1490 cm^{-1} band are related to the binding of non-histone proteins in the large grooves.

Raman spectroscopy has also been applied to the analysis of the B-Z transformation in synthetic polymers induced by drug binding. For example, it was shown that binding of *trans*-dichlorodiamine platinum to poly(dG-dC)·poly(dG-dC) appeared to inhibit the right-to-left

handed transition whereas the antitumour drug *cis*-dichlorodiamine platinum was found to reduce the salt requirement for adopting a left-handed modified Z-like conformation and rendered the transition essentially non-cooperative.

A Raman spectroscopic method to obtain information about dynamic aspects of nucleic acid secondary structure monitors the deuterium exchange of the C-8 purine hydrogen. The exchange rates can be determined from the time-dependent intensity increase of the bands characteristic for the deuterated bases. As the exchange process depends on the chemical environment and the solvent accessibility for the individual bases, these data allow differentiation of helical structures.

Pyrimidine and purine bases of nucleic acids have electronic absorptions in the range between 200 and 280 nm. Using excitation lines in this spectral region, RR spectra of nucleic acids exclusively display bands of in-plane ring modes of the bases without any interference of bands from the backbone. However, a selective enhancement of modes originating from purine or pyrimidine bases is not possible so that the practical use of UV RR spectroscopy for structural investigations of nucleic acids is limited. Whereas, RR spectroscopy can be employed to probe drug-DNA interactions if the electronic transition of the drug is shifted towards the near-UV and visible region. In this way, intercalation of adriamycin by DNA was studied using different excitation lines to probe either the DNA Raman spectrum (364 nm) or the RR spectrum of the bound drug (457 nm).

Membranes

Natural biological membranes represent multicomponent systems as they include a large variety of different lipids, proteins and carbohydrates. This heterogeneity is a serious obstacle to the interpretation of Raman spectra. Thus, the majority of spectroscopic studies have focused on liposomes which are taken as models for biological membranes.

A study of the fluidity and phase transition of the lipid hydrocarbon chain suggests a sensitive marker band originates from the longitudinal acoustic mode (LAM) at 100–200 cm^{-1} , which corresponds to an accordion-like stretching of the entire molecule along its long axis. The frequency of this mode depends on the all-*trans* chain length and is sensitive to gauche rotations of the chain. The LAM is quite strong in pure hydrocarbons. However, it is difficult to observe due to its proximity to the laser line so that in the Raman spectra of phospholipid dispersions, it could be detected only in a few cases, that at low water content and low temperature.

The skeletal optical modes between 1050 and 1150 cm^{-1} and the ratio of the C-H stretching bands at 2850 and 2885 cm^{-1} were used to detect membrane order

perturbations induced by the incorporation of small hydrophobic molecules in the bilayer. The intensity at 1130 cm^{-1} is thought to be a measure for the number of all-*trans* sections involving more than three carbon atoms. For phosphatidylcholine vesicles, it was found that the intensity of this band relative to either the 1660 cm^{-1} band or the C–N choline stretching at 718 cm^{-1} could be used to monitor both phase transitions and gradual melting of the lipids. Changes of a stiffening of hydrocarbon chains, for example by binding of divalent cations to the phosphate head groups of phosphatidylcholines is inferred from alterations of the intensity ratio of the 1064 and 1089 cm^{-1} bands.

Interactions of membranes with larger molecules are difficult to probe by Raman spectroscopy unless selectivity can be increased by taking advantage of the RR effect. This has been demonstrated in studies on drug–membrane interactions by tuning the excitation line in resonance with the electronic transition of the drug molecule, for example amphotericin.

Dynamics of Biomolecules

Operating in the time-resolved domain, RR spectroscopy can be employed to probe the dynamics of biological systems. Hence, such studies can provide simultaneously kinetic and structural data. In many cases, time-resolved RR spectroscopy, albeit technically demanding, may represent the method of choice for elucidating the molecular mechanisms of biological reactions.

Photoinduced Processes

Bacterial retinal proteins such as bacteriorhodopsin and halorhodopsin act as light-driven ion pumps. The ion gradient that is generated across the membrane is then converted into chemical energy (i.e. synthesis of adenosine triphosphate). The ion translocation is linked to a photoinduced reaction cycle of the retinal chromophore. The photophysical and kinetic properties as well as the stability of this class of proteins make them an ideal system for time-resolved RR spectroscopic studies. Moreover, these proteins represent suitable objects for developing and optimizing time-resolved spectroscopic techniques. The main advantage is the reversibility of the photoinduced reaction cycle, that is the system comes back to the parent state in a few milliseconds after the primary photochemical event. Thus, time-resolved RR spectra can be accumulated continuously since the ‘fresh sample’ condition is readily established. This condition ensures that the protein is always in the same state when irradiated by the exciting laser beam.

There are two approaches for time-resolved RR spectroscopy of these retinal proteins. Using CW-excitation, a

time resolution down to 100 ns can be achieved by rapidly moving the sample through the laser focus (rotating cell, capillary flow system). Pulsed laser excitation can provide a time resolution even in the sub-picosecond range depending on the pulse width of the laser. In both methods, intermediate states are probed in dual-beam experiments with the probe beam irradiating the sample after a delay time δ with respect to the photolysis beam which initiates the reaction cycle. The systematic variation of δ allows the determination of the photocycle kinetics which, along with the structural data derived from the RR spectra, can provide a comprehensive picture of the dynamics of the protein. **Figure 3** shows a selection of time-resolved RR of halorhodopsin. The bands displayed in these spectra are diagnostic for the retinal configuration (C=C stretching) and confirm that the photoreaction includes the isomerization from the all-*trans* to the 13-*cis* configuration.

Figure 3 Time-resolved RR spectra of halorhodopsin from *Natronobacterium pharaonis* obtained in single (probe only, 514 nm) and dual-beam experiments with variable delay times δ of the probe laser (514 nm) relative to the pump laser (600 nm).

Redox Processes

Cytochrome *c* oxidase, a membrane-bound enzyme in the respiratory chain of aerobic organisms, reduces oxygen to water. This process which takes place at the binuclear metal centre constituted by a haem a_3 and a Cu ion runs via several intermediate states with life times in the micro- and millisecond range. Technical improvements now make it possible to monitor this reaction sequence by time-resolved RR spectroscopy using rapid flow systems. The starting point of the experiments is the thermally stable carbon monoxide complex of the reduced enzyme in oxygen-saturated solution. This complex is photodecomposed by a laser beam so that oxygen can bind to the catalytic centre constituting the time 'zero' of the reaction sequence. The various intermediates are probed by a second laser beam irradiating the (photolysed) sample volume after a delay time. The oxygen-sensitive vibrational modes which can readily be identified based on the $^{18}\text{O}/^{16}\text{O}$ isotopic shifts give insight into the nature of the various intermediates and, hence, into the molecular mechanism of the oxygen reduction. A particularly interesting technical approach for these studies is based on an artificial cardiovascular device designed to maintain a continuous enzymatic reaction. Thus, it is possible to accumulate the RR signals during a sufficiently long period of time using a minimum amount of sample.

Living Cells and Biomedical Applications

Recent progress in laser technology and signal detection has substantially increased the sensitivity of Raman spectroscopy. This is a prerequisite for the development of Raman microspectroscopy and Raman imaging which has opened a new field for the application of Raman spectroscopy in biological and medical research. A particularly powerful method has been introduced by Greve and co-workers who combined Raman spectroscopy with confocal microscopy which allows the measurement of spatially resolved Raman spectra with a lateral resolution of less than 0.5 μm . The technique makes use of sensitive CCD detection systems by probing either the intensity of a marker band in two (spatial) dimensions (global imaging) or a complete spectrum in one dimension (line-scan imaging). In these experiments, low energy excitation ($> 600\text{ nm}$) has to be employed and the power of the tightly focused laser beam must be reduced as far as possible to avoid photoinduced degradation of the biological objects. In this way, it is possible to study single living cells and to obtain Raman spectra of the cytoplasm and the nucleus separately. The spectral information allows determination of the DNA conformation, the relative content of the individual nucleic acid bases and the DNA/protein ratio. Furthermore, less abundant

biomolecules such as carotenoids or haem enzymes or nonfluorescent drugs (e.g. cobalt octacarboxyphthalocyanine) can be detected by taking advantage of the RR effect. These studies are particularly promising for elucidating metabolic processes in cells.

This method has also been applied to medical problems related to disease diagnosis (e.g. atherosclerotic plaque) or optimization of medical treatment (e.g. bone implants). However, medical applications of Raman spectroscopy do not necessarily require the combination with microscopy. Numerous studies have indicated that based on the analysis of Raman spectra by statistical methods it is possible to differentiate between normal and pathological tissues. Despite the substantial technical improvements, the intrinsically low sensitivity of Raman spectroscopy constitutes a limit for general applicability. Fluorescent samples may impose an additional constraint, which, however, can be overcome by near-infrared (1064 nm) Fourier-transform Raman spectroscopy and microscopy. In summary, it appears that for special medical applications Raman spectroscopic techniques may become a powerful diagnostic tool in clinical situations.

Introduction

Investigation of biofluid composition provides insight into the status of a living organism in that the composition of a particular fluid carries biochemical information on many of the modes and severity of organ dysfunction. One of the most successful approaches to biofluid analysis has been the application of NMR spectroscopy. Thus, NMR spectroscopy of biofluids is a cornerstone of metabonomics that along with proteomics, transcriptomics and genomics forms the basis of systems biology, the current approach to providing a holistic understanding of biochemical changes that occur in disease and as a function of diet, lifestyle and other environmental influences.

The complete assignment of the ^1H NMR spectrum of most biofluids is not possible owing to the enormous complexity of the matrix. However, the assignment problems vary considerably between biofluid types. For instance, seminal fluid and blood plasma are highly regulated with respect to metabolite composition and concentrations, and the majority of the NMR signals have been assigned at 600 and 750 MHz for normal human individuals. Urine composition is much more variable because it is normally adjusted by the body in order to maintain homeostasis, and hence complete analysis is much more difficult. There is also enormous variation in the concentration range of NMR-detectable metabolites in urine samples. With every new increase in available spectrometer frequency, the number of resonances that can be resolved in a biofluid increases, and although this has the effect of solving some assignment problems, it also poses new ones. Furthermore, problems of spectral interpretation arise due to compartmentation and binding of small molecules in the organized macromolecular domains that exist in some biofluids such as blood plasma and bile.

All biological fluids have their own characteristic physicochemical properties, and a summary of some of these is given in **Table 1** for normal biofluids. These partly dictate the types of NMR experiment that may be employed to extract the biochemical information from each fluid type. An illustration of the complexity of biofluid spectra, and hence the need for ultrahigh field measurements, is given in **Figure 1**, which shows 800 MHz ^1H NMR spectra of normal human urine, bile, and blood plasma.

It is clear that even at the present level of technology in NMR, it is not yet possible to detect many important biochemical substances in body fluids, for example, hormones, because of problems with sensitivity, dispersion, and dynamic range, and this area of research will continue to be technology limited. With this in mind, it would seem prudent to interpret quantitative ^1H NMR measurements of intact biological materials and assignment of resonances in 1D spectra with considerable caution even when measured at ultrahigh field.

This article thus surveys the various metabolites that have been detected by NMR spectroscopy in a variety of biofluids and provides information on the methods used for identifying them. A comprehensive list of these metabolites and their NMR parameters is given.

Table 1 Normal biofluids and their physicochemical properties

Biofluid	Function	Water content ^a	Viscosity	Protein content ^b	Lipid content ^c	Peak overlap ^d
Urine	Excretion Homeostasis	+	^e	^e	^e	^e
Bile	Excretion Digestion	+	+	+	+	+

^aRelative water intensity when compared with concentrations of metabolites of interest.

^bIn biofluids with high protein or lipid contents, spin-echo spectra must normally be employed to eliminate broad resonances.

^cA subjective indication of spectral crowding (at 600 MHz) due to abundance of endogenous metabolites with a wide range of shifts.

^dPresence of cells and process of cell sedimentation gives rise to magnetic field inhomogeneity problems.

^eNot a limiting factor.

Resonance Assignment in NMR Spectra of Biofluids

Usually in order to assign ¹H NMR spectra of biofluids, comparison is made with spectra of authentic materials and by standard addition to the biofluid sample. Additional confirmation of assignments is usually sought from the application of two-dimensional (2D) NMR methods, particularly COSY and TOCSY and, inverse-detected heteronuclear correlation methods such as HMQC and HSQC. In addition, the application of the 2D J-resolved (JRES) pulse sequence is useful for spreading out the coupling patterns from the multitude of small molecules in a biofluid. Even 2D correlation NMR spectra of complex biofluids can show much overlap of cross-peaks and further editing is often desirable. Thus, simplification of 1D and 2D NMR spectra of biofluids can also be achieved using (1) spin-echo methods particularly for fluids containing high levels of macromolecules (*T*₂ editing), (2) editing based on *T*₁ relaxation time differences, (3) editing based on diffusion coefficient differences, and (4) multiple quantum filtering.

One major advantage of using NMR spectroscopy to study complex biomixtures is that measurements can often be made with minimal sample preparation (usually with only the addition of 5–10% D₂O) and a detailed

analytic profile can be obtained on the whole biological sample. This in turn requires good methods for suppressing solvent resonances.

Detailed ¹H NMR spectroscopic data for a wide range of low molecular weight metabolites found in biofluids are given in Table 2. Lists of metabolites that have been detected in biofluids by NMR spectroscopy are also available on-line together with their NMR parameters and often the full NMR spectra as well. The databases known as the Human Metabolome Database and the Madison Metabolomics Consortium Database are particularly useful. Their website addresses are given at the end of this article.

NMR Studies of Dynamic Interactions

Although NMR spectroscopy of biofluids is now well established for probing a wide range of biochemical problems, there are still many poorly understood physicochemical phenomena occurring in biofluids, particularly the subtle interactions occurring between small molecules and macromolecules or between organized multiphasic compartments. The understanding of these dynamic processes is of considerable importance if the full diagnostic potential of biofluid NMR spectroscopy is to be

Figure 1 800 MHz ^1H NMR spectra of control human biofluids; (a) urine, (b) gall bladder bile, and (c) blood plasma. Reproduced from Lindon JC, Nicholson JK, and Everett JR (1999) NMR spectroscopy of biofluids. *Annual Reports on NMR Spectroscopy* 38: 1–88, with permission from Academic Press.

realized. Typically, it is now possible to study enzymatic reactions, chemical reactions and biofluid instability, microbiologic activity in biofluids, macromolecular binding of small molecules, membrane-based compartmentation, metal complexation, and chemical exchange processes.

NMR Spectroscopy of Blood Plasma and Whole Blood

NMR Peak Assignments

The physicochemical complexity of plasma shows up in its ^1H NMR spectra by the range of linewidths of the signals. This means that a number of different multiple pulse NMR experiments and physicochemical interventions must be applied to extract useful biochemical information. Numerous high-resolution ^1H NMR studies have been performed on the biochemistry of blood and its various cellular components and plasma. The physical properties of whole blood pose serious limitations on

direct NMR investigations, but packed erythrocytes yield more useful information on cell biochemistry. Well-resolved spectra are given by plasma, and ^1H NMR measurements on blood serum and plasma can provide much useful biochemical information on both low molecular weight metabolites and macromolecular structure and organization.

In blood plasma, the ^1H NMR peaks of metabolites, proteins, lipids, and lipoproteins are heavily overlapped even at 800 MHz (**Figure 1**). Most blood plasma samples are quite viscous, and this gives rise to relatively short T_1 relaxation times for small molecules, which allows relatively short pulse repetition cycles without signal saturation. The spectral profile can be simplified by use of spin-echo experiments with an appropriate T_2 relaxation delay to allow signals from broad macromolecular components and compounds bound to proteins to be attenuated. By the early 1980s, many metabolites had been detected in normal blood plasma although assignments were, in general, based on the observation of only one or

^aMain biofluid in which compounds are found or have been observed; A, C, P, S, and U refer to observation in amniotic fluid, CSF, serum, seminal fluid, and urine, respectively.

^bVaries according to the presence of divalent metal ions (especially Ca, Mg, and Zn).

^cHighly variable over physiological pH range.

^dSignificant shift differences due to the formation of fast-exchanging complexes with divalent metal ions in biofluids.

^eNot normally observed in biofluids because of low stability.

two resonances for each metabolite. In addition, peaks from certain macromolecules such as α_1 -acid glycoprotein (*N*-acetyl neuraminic acid and related sialic acid fragments) have been assigned and used diagnostically, in particular their *N*-acetyl groups that give rise to relatively sharp resonances presumably due to less restricted molecular motion. The signals from some lipid and lipoprotein components, for example very low density lipoprotein (VLDL), low-density lipoprotein (LDL), high-density lipoprotein (HDL), and chylomicrons, have also been partially characterized.

For normal plasma at pH 7, the largest peak in the spectral region to high frequency of water is that of the α -anomeric H1 resonance of glucose at $\delta 5.223$ (which provides a useful internal chemical shift reference). In spectra of normal human and animal plasma, there are few resonances in the chemical shift range to high frequency of $\delta 5.3$ when measured in the pH range 3–8.5. However, on acidification of the plasma to pH < 2.5, resonances from histidine and phenylalanine become detectable. Experiments with model solutions suggested that serum albumin has a high capacity for binding aromatic amino acids and histidine at neutral pH, and this is responsible for their NMR invisibility in normal human blood plasma. Serum albumin also binds a large number of other species of both endogenous and xenobiotic origin. Even commercial 'purified' bovine serum albumin (BSA) can be shown to contain a significant

amount of bound citrate and acetate, which become NMR detectable in BSA solutions at pH 2. Acidification of human plasma also renders citrate NMR detectable in spin-echo spectra as it becomes mobilized from the protein-binding sites. Through the increased spectral dispersion available from the use of higher observation frequencies and through the use of a variety of 2D methods, the assignment of resonances in blood plasma spectra in normal individuals is now extensive (see **Table 2**).

Blood plasma also has intrinsic enzymatic activities although many of these are not stable (particularly if the sample is not frozen immediately on collection). It has been noted that under certain pathological conditions, such as those following liver or kidney damage, enzymes that are present at elevated levels in the plasma because of leakage from the damaged tissue can cause NMR-detectable alterations to spin-echo spectra of plasma.

Molecular diffusion coefficients are parameters that are not related directly to NMR spectral intensities under normal conditions. However, molecular diffusion can cause NMR signal intensity changes when pulsed field gradients are applied during the NMR experiment. A number of pulse sequence developments have meant that measurement of diffusion coefficients is relatively routine. The editing of ^1H NMR spectra of biofluids based on diffusion alone or on a combination of spin relaxation and diffusion has been demonstrated. This

approach is complementary to the editing of ^1H NMR spectra based on differences in T_1 and T_2 . Methods for editing TOCSY NMR spectra of biofluids have been proposed based on differences in molecular diffusion coefficients, and this has been termed diffusion edited TOCSY (DETOCSY).

Much study has been devoted to the problem of lipoprotein analysis in blood plasma using ^1H NMR spectroscopy. This has been comprehensively reviewed by Ala-Korpela. Lipoproteins are complex particles that transport molecules normally insoluble in water. They are spherical with a core region of triglyceride and cholesterol ester lipids surrounded by phospholipids in which various proteins known as apolipoproteins are embedded. In addition, free cholesterol is found in both the core and surface regions. The lipoproteins are in a dynamic equilibrium with metabolic changes going on *in vivo*. Lipoproteins are usually classified into five main groups: chylomicrons, VLDL, LDL, intermediate-density lipoprotein (IDL), and HDL based on physical separation using centrifugation. Based on the measurement of ^1H NMR spectra of the individual fractions and using line-shape fitting programs, it has been possible to identify the chemical shifts of the CH_2 and CH_3 groups of the fatty acyl side chains. Quantification can be carried out using either time-domain or frequency-domain NMR data. The usefulness of ^1H NMR spectra for lipoprotein analysis and ^{31}P NMR spectroscopy for phospholipid analysis in blood plasma has been explored. More recently, a neural network software approach has been used to provide rapid lipoprotein analyses.

^1H NMR Spectroscopy of Whole Blood and Red Blood Cells

Single-pulse ^1H NMR measurements on whole blood give very little biochemical information owing to the presence of a broad envelope of resonances from hemoglobin and plasma proteins. Spin-echo spectroscopy of whole blood can give rise to moderately well-resolved signals from plasma metabolites and those present inside erythrocytes, notably glutathione, but whole blood spectra are not easily reproducible because of erythrocyte sedimentation, which progressively (within a few minutes) degrades the sample field homogeneity during the course of data collection. Furthermore, there are substantial intracellular/extracellular field gradients that majorly contribute to the T_2 relaxation processes for the nuclei of molecules diffusing through those gradients, and very weak spectra are obtained. Spin-echo NMR measurements on packed erythrocyte samples do give rise to well-resolved signals from intracellular metabolites, and a variety of transport and cellular biochemical functions can be followed by this method.

One major parameter that can be obtained from NMR is the intracellular pH, and this has been measured for erythrocytes by ^1H NMR spectroscopy using a suitable ^1H NMR pH indicator that has an NMR chemical shift which varies with pH in the range desired. Candidates include the C2-H protons from histidines in hemoglobin, but an exogenous compound can be added as an indicator.

The transport of substances between the inside and outside of red cells can be monitored using NMR if the resonances from the two environments have different chemical shifts or intensities. Also, resonances outside the cell can be selectively broadened by the addition of paramagnetic species that do not cross the red cell membrane. Those used include the ferric complex of desferrioxamine, dysprosium-DTPA, and the copper-cyclohexanediaminetetraacetic acid complex. To measure the rate of influx of a compound into red cells, the compound is added with the paramagnetic agent to a red cell suspension and the intensity of the resonance from the intracellular component is monitored as a function of time. This approach has been used to study the transport of glycerol, alanine lactate, choline, and glycylglycine. The timescale that can be addressed covers the range of milliseconds to hours.

Rabenstein has reviewed much of the work in the area of red blood cell NMR spectroscopy. More recently, diffusion coefficient measurement has been used to study the binding between diphosphoglycerate and hemoglobin inside intact red blood cells.

NMR Spectroscopy of Human and Animal Urine

Sample Preparation and NMR Assignments

The composition and physical chemistry of urine are highly variable both between species and within species according to lifestyle. A wide range of organic acids and bases, simple sugars and polysaccharides, heterocycles, polyols, low molecular weight proteins, and polypeptides is present together with inorganic species. Many of these moieties also interact to form complexes, some of which are amenable to NMR study and may undergo chemical exchange reactions on a variety of different timescales. The ionic strength of urine varies considerably and may be high enough to adversely affect the tuning and matching of the RF circuits of a spectrometer probe, particularly at high field strengths. The presence of high concentrations of protein in the urine, for example, due to renal glomerular or tubular damage, can result in the broadening of resonances from low molecular weight compounds that may bind to these urinary proteins.

Urinary pH values may vary from 5 to 8, according to the physiological condition in the individual, but usually lie between 6.5 and 7.5. Urine samples should

therefore be frozen as soon as possible after collection if NMR measurements cannot be made immediately. When experiments involve collections from laboratory animals housed in metabolic cages, urine samples should be collected into receptacles that either are cooled with dry ice or have a small amount of sodium azide present as a bactericide. However, both these procedures may inhibit or destroy urinary enzymes that may frequently be assayed by conventional biochemical methods for assessment of kidney tubular integrity in toxicological experiments. Urinary pH values are unstable because of the progressive and variable precipitation of calcium phosphates that may be present in the urine close to their solubility limits. One solution to this problem is the addition of 100–200 mM phosphate buffer in the D₂O added for the lock signal followed by centrifugation to remove precipitated salts. This has the effect of normalizing the pH to a range of 6.7–7.6, which is stable for many hours during which NMR measurements can be made. Few metabolites (except for histidine and citrate) show major chemical shift variations over this pH range.

The vast majority of urinary metabolites have ¹H T₁ relaxation times of 1–4 s. Thus, the general rule of applying a 5 × T₁ relaxation delay between successive 90° transients to obtain >99% relaxation and hence quantitative accuracy cannot be applied routinely. Instead, by using 30–45° pulse angles and leaving a total T₁ relaxation delay of 5 s between successive pulses, spectra with good signal-to-noise ratios can usually be obtained for most metabolites in 5–10 min at high field with a generally low level of quantitative signal distortion. It has become standard practice to replace simple solvent resonance presaturation with pulse methods, which either induce such saturation or leave the solvent water resonance unexcited, and one popular method involves using simply the first increment of the 2D NOESY pulse sequence.

A vast number of metabolites may appear in urine samples, and problems due to signal overlap can occur in single-pulse experiments. The magnitude of the signal assignment problem in urine is also apparent at ultrahigh field. There are probably >5000 resolved lines in single-pulse 750 or 800 MHz ¹H NMR spectra of normal human urine (**Figure 1**), but there is still extensive peak overlap in certain chemical shift ranges, and even at 800 MHz many signals remain to be assigned. The dispersion gain at 800 MHz even over 600 MHz spectra is particularly apparent in 2D (or 3D) experiments that can be used to aid signal assignment and simplify overlapped spectra. Many of the endogenous compounds that have been detected in NMR spectra of human and animal urines are shown in **Table 2**.

The biochemical composition of urine varies considerably from species to species and also with age as

almost all species have age-related changes in renal function. Rats and other rodents have much higher levels of taurine, citrate, succinate, 2-oxoglutarate, and allantoin than humans. Rat urine (and that of other rodents) is generally much more concentrated than human urine, and so NMR signal-to-noise ratios may be better for many metabolites. All animals have physiological processes that are modulated by circadian rhythms. These include excretory processes, and the urinary composition of an animal may vary considerably according to the time over which it is collected. Given these types of variation, it is obviously of paramount importance to have closely matched (and in many cases timed) control samples where toxicological or disease processes are being studied. Dietary composition also affects the urinary metabolite profiles of humans and animals, and it is important to distinguish these from disease-related processes in clinical or toxicological studies. For example, persons consuming large quantities of meat/poultry before urine collection may have NMR-detectable levels of carnosine and anserine in their urine, consumption of cherries is associated with elevated urinary fructose, and consumption of shellfish and fish is associated with high levels of betaine and trimethylamine in the urine. The 500 and 600 MHz ¹H NMR spectra of neonate urines are characterized by strong signals from amino acids, organic acids, amines, sugars, and polyols. In particular, high concentrations of *myo*-inositol have been detected in both pre- and full-term urines. This is an important intracellular organic osmolyte in renal cells, present in high concentrations in the renal inner medulla.

NMR Spectra of Urine in Disease

Given the serious outcome of many inborn errors of metabolism, if not diagnosed and treated at an early stage, there has been a search for a rapid, sensitive, and general method for the detection and diagnosis of inborn errors of metabolism in neonates. Conventional methods including specific enzyme assays and gas chromatography/mass spectrometry are sensitive but time consuming, involve considerable sample preparation, and are not general. However, NMR spectroscopy of biofluids has been shown to be a very powerful and general method for the detection of inborn errors of metabolism, and many disorders have been studied by the use of biofluid NMR.

A good example is provided by the spectra from individuals with a deficiency in methylacetoacetyl-CoA thiolase (MACT). The conversion of 2-methylacetoacetyl-CoA into acetyl-CoA and propionyl-CoA is inhibited, and an accumulation of abnormal catabolic products is observed in the urine. Both 1D and 2D ¹H NMR spectroscopy have been used to investigate the urinary metabolites of patients with this disorder. The urine spectra

from the patients clearly showed the presence of both 2-methyl-3-hydroxybutyrate and tiglylglycine, which is characteristic for MACT deficiency due to the buildup of metabolites close to the position of enzyme deficiency.

High-field ^1H NMR spectroscopy has shown itself to be a very powerful tool with which to diagnose inborn errors of metabolism and to monitor the clinical response of patients to therapeutic interventions. Characteristic patterns of abnormal metabolites are observed in the patient's urine for each disease. The main advantages of using ^1H NMR spectroscopy in this area are its speed, lack of sample preparation, and the provision of non-selective detection for all the abnormal metabolites in the biofluid regardless of their structural type, providing only that they are present above the detection limit of the NMR experiment.

Evaluation of Toxic Effects of Xenobiotics Using NMR Spectroscopy of Urine

The successful application of ^1H NMR spectroscopy of biofluids to study a variety of metabolic diseases and toxic processes has now been well established, and many novel metabolic markers of organ-specific toxicity have been discovered. The method is based on the fact that the biochemical composition of a biofluid is altered when organ damage occurs. This is particularly true for NMR spectra of urine in situations where damage has occurred to the kidney or liver. It has been shown that specific and identifiable changes can be observed, which distinguish the organ that is the site of a toxic lesion. Also it is possible to focus on particular parts of an organ such as the cortex of the kidney and even, in favorable cases, on very localized parts of the cortex. Finally, it is possible to deduce the biochemical mechanism of the xenobiotic toxicity, based on a biochemical interpretation of the changes in the urine.

Many studies of toxicity have now been undertaken using NMR spectroscopy-based metabonomics. Often these involve the use of multivariate statistics or pattern recognition algorithms.

The first studies using pattern recognition (PR) to classify biofluid samples used a simple scoring system to describe the levels of 18 endogenous metabolites measured by ^1H NMR spectroscopy of urine from rats that were either in a control group or had received a specific organ toxin that affected the liver, the testes, the renal cortex, or the renal medulla. The data were used to construct nonlinear maps and various types of principal components (PC) scores plots in two or three dimensions. The samples were divided into two subsets, a training set and a test set. This study showed that samples corresponding to different organ toxins mapped into distinctly different regions and that in particular the renal cortical

Figure 2 A plot of PC1 versus PC2 for a set of rat urine samples using simple scored levels of 16 metabolites as the descriptor set. A cluster of renal cortical toxins is seen at the left, whereas the testicular and liver toxins are to the right. At the bottom the two renal papillary toxins (BEA and PI) appear to cluster with liver toxins (ALY and ANIT) but are well separated in the third principal component. Reproduced from Lindon JC, Nicholson JK, and Everett JR (1999) NMR spectroscopy of biofluids. *Annual Reports on NMR Spectroscopy* 38: 1–88, with permission of Academic Press.

and renal medullary toxins showed good separation (Figure 2).

In addition, the NMR–PR approach has been used to investigate the time course of metabolic urinary changes induced by two renal toxins. In this case, toxic lesions were induced in rats by a single acute dose of the renal cortical toxin mercury(II) chloride and the medullary toxin 2-bromoethanamine. The onset, progression, and recovery of the lesions were also followed using histopathology to provide a definitive classification of the toxic state relating to each urine sample. The concentrations of 20 endogenous urinary metabolites were measured at eight time points after dosing. A number of ways of presenting the data were investigated, and it was possible to construct PC scores plots that showed metabolic trajectories quite distinct for the two toxins. These showed that the points on the plot can be related to the development of, and recovery from, the lesions. These trajectories allowed the time points at which there were maximal metabolic differences to be determined and provided visualization of the treated groups of animals.

NMR Spectroscopy of Cerebrospinal Fluid

Because of the low protein content of normal human cerebrospinal fluid (CSF), it is possible to use single-pulse ^1H NMR experiments to obtain biochemical information without recourse to the spin–echo techniques often required for studies on blood and plasma. However,

where serious cerebral damage has occurred, or in the presence of an acute infection, spectra may become dominated by broad resonances from proteins. Problems may also arise from protein binding and metal binding of some metabolites, with a consequential broadening of their proton resonances.

There are a number of ^1H NMR studies of CSF in the literature. Also, it has been shown that high-quality 2D ^1H NMR spectra can be obtained from human CSF and that changes in NMR patterns can be roughly related to disease states in the donor. Examination of a number of *ex vivo* control samples showed high consistency in the aliphatic region of the 1D ^1H NMR spectra of CSF, and many assignments could be made by inspection. Diseases studied using NMR spectra of CSF include lumbar disk herniations, cerebral tumors, drug overdose, diabetes, hepatic encephalitis, multiple sclerosis, AIDS dementia complex, Parkinson's disease, Creutzfeldt-Jakob disease, Guillain-Barré syndrome, and vitamin B₁₂ deficiency.

NMR Spectroscopy of Seminal Fluids

The 750 MHz ^1H NMR spectra of seminal fluid obtained from a healthy individual are complex, but many of the signals have been assigned (see Table 2). Fresh undiluted seminal fluid gives rise to NMR spectra with very broad and poorly resolved signals due to the presence of high concentrations of peptides (which are cleaved to amino acids by endogenous peptidase activity) and the high viscosity of the matrix. The complexity of the biochemical composition of seminal fluids together with their reactivity poses a number of assignment and quantitation problems. Some metabolite signals in seminal fluids also appear to have anomalous chemical shifts when compared to simple standard solutions measured at the same pH or even when compared to other body fluids. The application of 2D NMR methods has been shown to be very useful in the case of seminal fluids. An investigation of dynamic molecular processes that occur in seminal fluid has been undertaken using ^1H NMR spectroscopy. Reactions that could be followed included hydrolysis of phosphorylcholine and nucleotides and zinc complexation.

In view of the importance of artificial insemination in farming, it is somewhat surprising that so few studies of animal seminal fluid have been reported. However, there are studies on boar seminal plasma giving details of resonance assignments.

Other studies of infertility include a procedure providing automatic diagnosis based on NMR spectroscopy and work on azoospermic subjects and prostate cancer. In addition, ^{31}P NMR spectroscopy has also been used to distinguish between semen from healthy and infertile men.

NMR Spectroscopy of Bile

NMR Spectroscopy of Bile and Dynamic Interactions of Metabolites

The single-pulse NMR spectra of bile are dominated by broad resonances that arise from bile acids that are present in mixed micelles with phospholipids and cholesterol (Figure 1). They are broad as a result of short spin-spin (T_2) relaxation times reflecting constrained molecular motions within micellar particles. On lyophilization and reconstitution with water, the molecular mobility of a number of biliary metabolites changes significantly because of disruption of the micellar compartments. In particular, the T_2 relaxation times of the aliphatic side chains of lipid moieties are increased in lyophilized bile, suggesting greater mobility of these molecules. Increases in signal intensities that occur on lyophilization reflect changes in compartmentation of molecules, which is related to the disruption/reorganization of the biliary micellar compartments. Signals from β -hydroxybutyrate, valine, and other branched chain amino acids do not contribute significantly to the ^1H NMR spectra of non-lyophilized bile, but resonances from these components are clearly resolved after lyophilization. The sharper signals in bile give rise to well-resolved 2D COSY spectra that allow a comprehensive assignment of the bile salt signals. The use of 800 MHz ^1H NMR spectroscopy and the combination of 1-dimensional and 2-dimensional NMR experiments have allowed a comprehensive set of assignments to be made (see 'Further Reading' section).

Variable temperature ^1H NMR studies of human bile show that considerable dynamic structural information is available, particularly at high fields. The micellar cholesteryl esters that are abundant in bile appear to show liquid crystal behavior, and it is possible to use NMR measurements to map the phase diagram for the complex biliary matrix.

A number of studies have used both ^1H and ^{13}C NMR spectroscopy of bile to aid characterization of its composition and structure. Thus, ^{13}C spectra of bile from fish exposed to petroleum have been studied. ^{31}P NMR spectra of human bile have also been investigated. ^1H NMR spectroscopy of bile has been used to investigate the micellar cholesterol content and lipids, and both ^1H and ^{31}P NMR have been used to study the distribution of lecithin and cholesterol.

NMR Spectroscopy of Miscellaneous Body Fluids

Amniotic and Follicular Fluids

The first study of human amniotic fluid using ^1H NMR spectroscopy detected 18 small molecule metabolites including glucose, leucine, isoleucine, lactate, and

creatinine. Following this, other studies used a combination of 1D and 2D COSY spectroscopy to assign resonances, assess NMR methods of quantitation, and investigate the effects of freezing and thawing. In addition, NMR results have been correlated with other clinical chemical analyses. A total of 70 samples were measured using ^1H NMR at 600 MHz at different stages of gestation and with different clinical complications, and significant correlations between the NMR spectral changes and maternal pre-eclampsia and fetal open spina bifida were observed. The effects of various pathological conditions in pregnancy have been investigated using ^1H NMR spectroscopy of human amniotic fluid. Several studies of amniotic fluid using ^{31}P NMR spectroscopy have also been carried out, principally to analyze the phospholipid content. One study of the metabolic profiling of ovarian follicular fluids from sheep, pigs, and cows has been reported.

Milk

Surprisingly, very little has been published on the NMR spectroscopy of milk, given that it is both a biofluid and a food substance. The studies generally focus on milk as a food, and Belton has also reviewed the information content of NMR spectra of milk.

Synovial Fluid

^1H NMR has been used to measure the levels of a variety of endogenous components in the synovial fluid (SF) aspirated from the knees of patients with osteoarthritis (OA), rheumatoid arthritis (RA), and traumatic effusions (TE). The spin-echo NMR spectrum of SF shows signals from a large number of endogenous components. Many potential markers of inflammation could not be monitored because of their low concentrations or slow tumbling (e.g., hyaluronic acid, a linear polysaccharide that imparts a high viscosity to SF). The low molecular weight endogenous components showed a wide patient-to-patient variability and showed no statistically significant correlation with disease state. However, correlations were reported between the disease states and the SF levels of the *N*-acetyl signals from acute-phase glycoproteins. Correlations between the disease state and the levels and type of triglyceride in the SF have also been reported.

^{13}C NMR can also be used to monitor the SFs from patients with arthritis. In contrast to ^1H NMR studies, signals are seen from hyaluronic acid, the main determinant of the viscoelasticity of the SF, even though the molecular weight is in the region 500–1600 kD. ^{13}C NMR spectra of SFs from patients with RA, OA, TE, and cadaver controls have been compared with one another and with spectra of authentic hyaluronic acid, both before and after the incubation of the latter with hyaluronidase,

an enzyme that depolymerizes the hyaluronic acid. Depolymerization of the hyaluronic acid was accompanied by a decrease in the half-band widths of its ^{13}C resonances. The SF NMR spectra from patients with RA had sharper signals for the C-1 and C-1' carbons of hyaluronic acid than those from the osteoarthritic patients, which in turn exhibited sharper signals than those from the cadavers or the joint trauma patients. Thus, the degree of polymerization of hyaluronic acid was deduced to decrease in the following order: controls/joint trauma patients > osteoarthritic patients > RA patients. Since it is known that the consequence of hyaluronate depolymerization may be articular cartilage damage, it was concluded that ^{13}C NMR spectroscopy may be a valuable method for studying these clinically relevant biophysical changes in SF.

Aqueous Humor and Vitreous Humor

The first study by NMR spectroscopy on aqueous humor was on nine samples taken during surgery for other conditions, and NMR spectra were measured at 400 MHz. A number of metabolites were detected, including acetate, acetoacetate, alanine, ascorbate, citrate, creatine, formate, glucose, glutamine or glutamate, β -hydroxybutyrate, lactate, threonine, and valine. Following this, there have been a number of other studies. These include ^1H NMR spectra from aqueous humor of rabbits and codfish, ^{31}P NMR spectra of aqueous and vitreous humor from pigs, and ^{23}Na NMR spectra of vitreous humor. Finally, the penetration of dexamethasone phosphate into the aqueous humor has been followed using ^1H and ^{19}F NMR spectroscopy.

Saliva

Only limited studies using NMR spectroscopy of saliva have been reported. ^1H NMR spectroscopy of human saliva was used in a forensic study, and following this another group reported that only parotid gland saliva gave a well-resolved ^1H NMR spectrum showing significant circadian effects. No age- or sex-related differences were observed for saliva from healthy subjects, but marked differences were observed in cases of sialodentitis. Finally, the biochemical effects of an oral mouthwash preparation have been studied using ^1H NMR spectroscopy.

Digestive Fluids

The analysis of pancreatic juice and small bowel secretions using ^1H NMR spectroscopy has been reported.

Pathological Cyst Fluid

An ^1H NMR study of the fluid from the cysts of six patients with autosomal-dominant polycystic kidney

disease (ADPKD) has been reported. ADPKD in adults is characterized by the slow progressive growth of cysts in the kidney, and when these cysts reach a large size, they can significantly distort the kidney and disrupt both the blood supply and the renal function. ADPKD is one of the commonest causes for renal transplantation in adults. The ^1H NMR spectra revealed a number of unusual features and showed the cyst fluids to be distinct from both blood plasma and urine. Unusually, the fluids from all patients contained high levels of ethanol, which was not related to consumption of alcoholic beverages or drug preparations. In general, there was little variation in the composition of the cyst fluids as revealed by ^1H NMR, although the protein signal intensity did vary somewhat. It was hypothesized that this constancy of composition reflected the chronic nature of the accumulation of the cyst fluid and a long turnover time of the cyst components, which thus has the effect of averaging the compositions. The unique biochemical composition of the cyst fluids was ascribed to abnormal transport processes occurring across the cyst epithelial wall.

Introduction

Although, in principle, there is no difference between dispersive and Fourier transform spectrometers, the development of the latter instrument type has greatly contributed to the wealth of information, which has been obtained in the field of biological research over the past 25 years. The combination of a relatively simple optical layout of the Michelson interferometer, more powerful light sources, and detectors with improved characteristics has resulted in affordable instruments with excellent specifications (resolution, speed, and signal-to-noise ratio). In parallel with the development of infrared spectrometers, instrument manufacturers offer a large range of costly accessories that make the analysis of samples, which

are hard to analyze in KBr disk, in halogenated solvent or in Nujol dispersion much easier. From a viewpoint of sampling, biological samples may impose problems because of the following reasons:

1. These typically are present in an aqueous environment, and water strongly absorbs infrared light.
2. The small physical size or small sample amount. Living cells are of the same order of magnitude, as the wavelength of infrared light.

Figure 1 illustrates the problems that arise when water is used as a solvent. The infrared spectrum of a CaF_2 liquid cell with a pathlength of $25\text{ }\mu\text{m}$, filled with water, shows strong absorbance bands around 3360 and 1643 cm^{-1} (Figure 1(a)).

To prevent saturation of the detector by the water signal, measurements in transmission mode should be carried out using a very short pathlength. Hereto, spacers are available for creating a cell with, for example, $6\text{ }\mu\text{m}$ pathlength. The band around 1643 cm^{-1} is reduced to such an extent (Figure 1(b)) that useful spectra can be obtained by subtracting a spectrum of water from the spectrum obtained from a real sample. It should be noted that filling such a cell with a viscous protein solution with a typical concentration of 2% might already prove rather difficult. In Table 1, optical properties of selected materials are collected, which are commonly employed for

Figure 1 Infrared absorption characteristics of water. A (solid line), using a CaF_2 transmission cell with a pathlength of $25\text{ }\mu\text{m}$; B (dotted line), same cell but with a pathlength of $6\text{ }\mu\text{m}$; C (dashed line), using a horizontal ATR with an IRE of germanium. The effective pathlength is much reduced, thus facilitating the subtraction of a solvent spectrum; D (dashed-dotted line), using a CaF_2 transmission cell with a pathlength of $25\text{ }\mu\text{m}$, but D_2O instead of water. The important amide region is essentially free of water signals, but as a result of the isotope effect, the bands are shifted toward other spectral regions.

Table 1 Properties of some commonly used window material and internal reflection elements (IRE) for measurements on aqueous solutions^a

Material	T range (μm)	Refractive index	Application	Remarks
AgCl	0.4–30	1.98 at 10 μm	Window	Do not use with metal spacers
BaF ₂	0.15–12.5	1.45 at 5 μm	Window	Limited T range
CaF ₂	0.13–10	1.40 at 5 μm	Window	
Ge	1.8–23	4.00 at 10 μm	IRE	
ZnSe	0.5–22	2.40 at 10 μm	IRE	

^aT range indicates the wavelength range for which transmission is higher than 10%.

infrared studies on aqueous samples. The choice of material is determined by the research question, for example:

1. Is chemical inertness of the window needed?
2. Is the study limited to a certain spectral range?

Using attenuated total reflection (ATR) infrared spectroscopy largely overcomes this problem. By passing infrared light through an internal reflection element (IRE), an evanescent wave occurs at the surface of this optical element, and depending on the angle of incidence, wavelength, and refractive indices of sample and IRE, the beam partially penetrates the sample where absorption occurs. Finally, the attenuated beam is back-reflected to the detector. As a consequence, an infrared spectrum of water, measured in ATR mode, only shows relatively weak water signals (**Figure 1(c)**). The penetration depth of a germanium IRE with an angle of incidence of 45° is approximately 0.39 μm. The effective pathlength is somewhat longer (two to three times the penetration depth, depending on crystal geometry), yet only a small water signal is obtained, compared to a transmission experiment. Several technical versions of ATR accessories do exist, that is single reflection, micro-ATR, horizontal, and vertical, but the most versatile ATR layout consists of a thermostated horizontal ATR unit with a sample compartment that can be divided by a dialysis membrane and one side of the membrane facing the IRE surface. A schematic cross-sectional view is given in **Figure 2**.

Since both compartments can be filled separately, the sample can be modified without being removed from the cell. Using a bath circulator, sample temperature can be adjusted from approximately –20 °C up to more than 60 °C, when using proper insulation of the unit. Through dialysis, one can, for example, administer ligands or adjust pH or other environmental factors. The only disadvantage of using such a device is the relatively large sample amount, which is needed to fully cover the surface of the ATR.

Figure 2 Schematic representation of a horizontal ATR with perfusion option. The sample (hydrated membrane film or protein solution) is in contact with the surface of the IRE and is confined by the dialysis membrane. By changing the composition of the solution in the upper perfusion compartment, one can modify the conditions (e.g., pH or addition of a ligand) in the sample compartment through dialysis, without removing the sample from the instrument.

Another phenomenon that should be kept in mind when using ATR is the fact that the penetration depth and effective pathlength varies over the spectrum. Hence, intensities obtained from both transmission and ATR spectra cannot be compared directly. However, since the relation between pathlength and frequency is known, a correction factor can be introduced to scale the spectra, for example, before a library search when identifying a sample of unknown composition.

Alternatively, one might use deuterium oxide (heavy water) as a solvent. Owing to the isotope effect, the bands at 3360 and 1643 cm^{–1} are downshifted toward 2540 and 1211 cm^{–1}, respectively (**Figure 1(d)**). Now the spectral ranges above 2800 cm^{–1} and around 1640 cm^{–1} are essentially free of solvent signals. Thus, lower sample concentration and larger pathlengths can be chosen. As a side effect, sample bands of polar functional groups may occur at lower wavenumbers because of H/D exchange. Other organic, highly polar solvents such as dimethyl sulfoxide (aprotic, i.e., acts only as a hydrogen bond acceptor) or trifluoroethanol (protic, i.e., can donate or accept hydrogen in hydrogen bonds) may be considered although these solvents also exhibit strong infrared absorption bands elsewhere in the spectrum and are known to induce structural changes, for example, in proteins.

However, if the research question allows, there is no objection against measurements of biological samples in the dehydrated state. This approach makes sample handling much easier and reduces the need for subtraction of a solvent spectrum. Notably, the secondary structure of proteins is hardly affected by dehydration since at this level, protein structure is governed by intramolecular interactions, namely, hydrogen bonding. It should be noted that under these conditions, the actual

tertiary protein structure may be impaired and that the protein under study is in a nonfunctional state. Yet for comparative purposes, this approach can be quite fruitful. A problem that arises when measuring biological samples as a dehydrated film is that the optical pathlength is not defined. This may hinder quantitative analyses in which absolute concentrations are to be determined. To address this problem, an internal standard with a known concentration can be added. Hereby, sample spectra can be scaled relative to the signal of the standard. Typically, potassium thiocyanate (0.4%) is employed in biological studies. Thiocyanate (SCN^-) shows a unique single band at 2060 cm^{-1} , that is well outside the spectral range in which most other bands are observed. In such a study, silver halides should not be used as a sample support since SCN^- reacts with this window material.

The reason that infrared spectroscopy has proven to be very successful in biology lies in the fact that many localized vibrations in biomacromolecules, which, of course, do not differ from other organic molecules, occur in the mid-infrared (MIR) spectral region, which can be detected by this spectroscopic technique. **Figure 3** shows characteristic vibrational spectra for the major biomacromolecules, that is, proteins, lipids, and carbohydrates.

From these survey spectra it is clear that these classes of compounds show distinct absorptions in different

regions although overlapping bands are practically always present. **Table 2** lists the major vibrational bands that are commonly employed in biological infrared spectroscopic research.

This article is devoted mainly to the application of MIR spectroscopy in biology. In several fields of biological research, near-infrared (NIR) spectroscopy is also increasingly being used with considerable success. This spectroscopic technique is based on the detection of vibrational overtones, occurring at wavelengths nearer to the visible red part of the electromagnetic spectrum. Differences and common features in both techniques will be discussed, but for detailed information one should consult other articles in this work, related to this subject.

Microbiological Applications

Because of the fingerprint-like properties of a vibrational spectrum, infrared spectroscopy was recognized as an excellent technique for the rapid identification of unknown samples. The easiest way to perform such a qualitative analysis is to collect the spectra of as many related samples as possible under specific conditions and to compare the spectrum of the unknown samples with this collection. The performance (speed and quality of

Figure 3 Survey spectra of major biological macromolecules. a, bacteriophage Pf1. The spectrum is dominated by the characteristic amide I and amide II bands originating from the major coat protein; b, 16:1,16:1-PC. Phospholipids show characteristic vibrational bands in several regions, the most important ones being the C–H stretching vibrations between 2850 and 2930 cm^{-1} , the $\text{C}=\text{O}$ stretching in the lipid headgroup around 1740 cm^{-1} , and the $\text{P}=\text{O}$ stretching in the lipid headgroup around 1235 cm^{-1} ; c, glucose. Spectra of carbohydrates are difficult to analyze because of the complexity of overlapping bands of C–O stretching and C–OH bending vibrations around 1100 cm^{-1} . This highly characteristic pattern can be used to identify the sugars, present in the sample.

Table 2 Characteristic bands, occurring in infrared spectra of biological samples^a

ν (cm^{-1})	Assignment	Mainly observed in:
± 2900	ν_{as} (C–H) in CH_2	lipids
± 2850	ν_{s} (C–H) in CH_2	lipids
± 1740	ν (C=O) in esters	lipids overlap with $\nu(\text{COOH})$ of Asp and Glu
± 1650	ν (C=O) or amide I	proteins protein backbone conformation
± 1540	δ (N–H) or amide II	proteins protein backbone conformation overlap with ν (C=C) in Tyr
± 1460	δ (C–H)	lipids
± 1400	ν_{s} (COO^-)	protein: Asp and Glu
± 1235	ν_{as} (PO_2^-)	phospholipids nucleic acids
± 1100	a.o. ν (C–OH) and δ (O–H)	carbohydrates

^a ν denotes a stretching vibration and δ a bending vibration. Subscripts as and s refer to antisymmetric and symmetric vibrations, respectively. Note: a.o. among others.

the result) of a library search largely depends on:

1. database size (e.g., peak tables or full spectra)
2. search algorithm (e.g., absolute or squared difference or derivative)
3. additional information (e.g., physical constants and other spectral data)

It should be clear that a search, based on peak tables, yields the fastest but less reliable result since slightly shifted peaks are already lost (a peak table results in data reduction). Nowadays, computer storage and memory are not very expensive, so that searches can be performed on libraries containing full spectra.

The Pearson correlation coefficient can be employed as a quantitative measure for the similarity between two spectra ($0 < R^2 < 1$ with the value of $R^2 = 1.000$ indicating a good correlation). This parameter can be obtained by comparing the absorbance of the reference and the unknown sample at each wavenumber. The sum of the squared differences immediately reveals the absence of relatively large signals in sample or reference spectra. Alternatively, an algorithm, employing a first derivative before calculation of the differences, might be useful for compensation of a drifting baseline. Hence, the settings of the search procedure may influence the outcome of the results. **Table 3** illustrates the use of a library search for determining the global secondary structure of a protein by comparison with a set of reference spectra of proteins with a known secondary structure.

In this simple simulated search, it is shown that the results change depending on the search algorithm. The

Table 3 Search parameters determine the outcome of a spectral search^a

^aA spectrum of photoreceptor membranes is matched against a spectral library of water-soluble proteins. Despite the presence of phospholipids, this approach characterizes the photoreceptor protein, opsin, as a mainly α -helical protein as is evident from the high ranking of myoglobin (correlation coefficient is 1.00).

procedure nevertheless correctly predicts a mainly α -helical structure for the unknown sample, despite the presence of phospholipids. However, the result does not signify that the secondary structure is equal to that of the reference protein. The ranking is based on overall spectral similarity. A better estimate of the secondary structure of proteins can be obtained by curve fitting the amide I and II bands.

An elegant and popular example of applying spectral library searches is the rapid identification of bacteria. By combining a library search with cluster analysis (not treated in this article), one can classify a sample of bacteria even down to the strain or subspecies level within a few minutes. This application and modifications hereof have found their use in the clinical chemical laboratory.

A major characteristic of any living organism is its capability to change its metabolism in response to genetic modification or interaction with its environment. The study of metabolomics is a logical approach after genomics and proteomics, respectively, dealing with gene expression and posttranslational control over enzyme activity. The challenge in all 'omics-fields' is to deal with large numbers of samples, small sample size or quantity, and large amounts of data. Although there is no single analytical technique available for detection and quantitation of all conceivable metabolites, infrared spectroscopy performs well when used for metabolic fingerprinting, that is, giving a

qualitative and semiquantitative estimate of the major components present in a sample. In most cases this means detection of proteins, (phospho-)lipids, carbohydrates, and possibly, selected metabolites.

When a well-resolved absorption band can be found in a spectrum, quantitation is most easily carried out using the Lambert–Beer law, which linearly relates concentration to the measured absorbance. Several variations of this theme for the infrared spectroscopic determination of protein, lipid, and carbohydrate can be found in the literature. In more complex samples with several components to be analyzed, this approach may prove unsuccessful. In these cases one has to determine concentrations based on the absorption of each component at several different wavenumbers. This approach is actually an extension of the Lambert–Beer law and is also known as multiple linear regression (MLR). A characteristic of this method is the need for several reference samples at various compositions during the calibration of the model.

Alternatively, the application of partial least square (PLS) regression can be considered. The outcome of such an analysis is a number of scores or coefficients corresponding to a set of virtual component spectra or so-called loading vectors, together making up the measured spectrum by linear combination. Relating the scores to the actual constituents in the sample requires calibration of the model, using a training set of spectra of samples in which the concentrations are known from other analytical methods. PLS regression yields quite accurate results, provided that the model is set up correctly. However, this may prove to be a difficult task.

Recently, genetic algorithms (GAs) and genetic programming (GP) have been developed and applied to infrared spectra of meat samples in order to detect microbial spoilage. Although the outline of these chemometric approaches is beyond the scope of this article, these methods employ explicit relations between the measured spectra and the desired parameter, for example, the onset or the level of spoilage or the number of bacteria that are present in the sample. After 16 h at a level of 10^7 g^{-1} bacteria present, the onset of proteolysis was demonstrated, based on the changing ratio of the absorbance at 1096 and 1683 cm^{-1} , originating from released free amines and protein amide groups, respectively.

More recently, interest in the biosorption of heavy metals by microorganisms has increased as judged by the number of published research papers in which the use of infrared spectroscopy was reported. Although the uptake of heavy metal ions was established using complementary spectroscopic techniques, documentation of the observed spectral changes remained questionable because presence and changes in lipids and protein, which are present in biomass, were neglected in several papers. When the major protein bands, amide I and amide II, are taken into

account, there is still discussion whether the changes are the result of protein oxidation, that is carbonylation, or denaturation by binding of metal ions, leading to protein secondary structural changes.

Botanical Applications

In the field of plant physiology, infrared spectroscopy has been intensively used for assessing the effects of dehydration on seeds and pollen in relation to the viability and germination properties after prolonged storage. Hereto, infrared microspectroscopy was applied to study thermodynamic properties and conformation of endogenous biomacromolecules in tissue of anhydrobiotic plants. The microscope is used to focus the infrared beam on a small section of the tissue, typically $10 \times 10 \mu\text{m}$, rather than to measure infrared spectra of intracellular components. For the latter purpose the spatial resolution of the instrument, which is related to the wavelength of the infrared light, does not suffice. By comparing amide I band profiles after rapid or slow drying of maize or carrot embryos, it was shown that in slowly dried samples, protein secondary structure is rather stable as compared to rapidly dried embryos, in which a relatively higher contribution by β -sheets around 1638 cm^{-1} was observed. The preservation of α -helical structure coincided with retaining viability after rehydration of the embryos. Similar results were obtained with alfalfa somatic embryos that were pretreated with the plant hormone abscisic acid (ABA). The results of these experiments are given in **Figure 4**.

In the absence of ABA, the slowly dried embryos also showed bands at 1638 and 1688 cm^{-1} , which are characteristic for β -sheet structures. These experiments demonstrated that slow drying is a prerequisite for preservation of viability and showed the involvement of ABA in maintaining a high content of α -helical proteins, which may aid in the protection of endogenous protein in the dehydrated state.

By recording the temperature-dependent shifts of vibrational bands, thermodynamic properties can be studied. These parameters can also be derived from differential scanning calorimetric (DSC) experiments, but infrared spectra contain information on individual macromolecular components present in the sample. For example, on raising the temperature, the band around 2851 cm^{-1} representing the symmetric stretching vibration in CH_2 groups, mainly occurring in (phospho-) lipids, shows a sigmoidal curve corresponding with the gel-to-liquid crystalline phase transition. The discontinuity is a result of the decreased van der Waals interaction between lipid acyl chains in the liquid crystalline state. **Figure 5** shows a few curves obtained from selected phosphatidylcholines. The gel-to-liquid

Figure 4 Deconvoluted FTIR spectra over the region 1700–1600 cm^{-1} of 30-day-old alfalfa somatic embryos, cultured with or without 20 μM ABA in DTP medium. The embryos were subjected to drying at an intermediate (a) or slow rate (b), after which IR spectra of the dried embryos were recorded. Reprinted from Sreedhar L, Wolkers WF, Hoekstra FA, and Bewley JD (2002). In vivo characterization of the effects of abscisic acid and drying protocols associated with the acquisition of desiccation tolerance in alfalfa (*Medicago sativa* L.) somatic embryos. *Annals of Botany (London)* 89: 391–400, with permission from Oxford Journals/Oxford University Press.

crystalline transition temperatures are obtained from the midpoint of the curves and are in correspondence with those obtained from DSC measurements.

Temperature-dependent changes in protein structure may present themselves differently in an infrared spectrum. By raising the temperature, one might observe an upshift of selected amide I components or the appearance of a new band around 1625 cm^{-1} , which can be attributed

to extended β -strands. This phenomenon normally occurs at higher, nonphysiological temperatures, but still is a characteristic feature of the protein under study. A feature that commonly remains undiscussed is the observation that with an upshifting amide I band, the amide II band shows a downshift. This can be explained by the fact that through a hydrogen bond, a $\text{C}=\text{O}$ group exerts a force on the hydrogen atom, thereby restraining the $\text{N}-\text{H}$ bending vibration. Hence, more energy is required for the bending vibration to occur, corresponding with a higher frequency. On raising the temperature, the hydrogen bond is weakened and consequently the $\text{N}-\text{H}$ bending vibration occurs at a lower frequency. A similar effect is found for the $\text{C}-\text{H}$ bending vibration around 1465 cm^{-1} . The band around 3300 cm^{-1} can be assigned to the OH stretching vibration, for example, in water and carbohydrates. When increasing the temperature, this band shows a bilinear curve, the inflection point representing the glass transition temperature, denoted T_g . The upshift of the OH stretching vibration is indicative of reduced hydrogen bonding strength between OH groups.

This latter approach is used in the analysis of a series of ABA-insensitive mutants of *Arabidopsis thaliana* seeds, which are desiccant tolerant but show a gradual decrease in viability (Figure 6).

The average strength of hydrogen bonding, as expressed by the wavenumber shift per temperature change (WTC in $\text{cm}^{-1} \text{ } ^\circ\text{C}^{-1}$, which is actually the first derivative of $\nu(\text{OH})$ versus temperature), could be related to the macromolecular stability in the glassy matrix. The most vulnerable mutant, *abi3-5*, showed a $\text{WTC} = 0.51$ and a protein denaturation onset at approximately 70 $^\circ\text{C}$, whereas the relatively stable *abi3-1* mutant showed an almost wild-type $\text{WTC} < 0.22$ and a denaturation onset temperature above 130 $^\circ\text{C}$.

The past few years have witnessed an enormous increase in the use of infrared spectroscopy in China. In this land with an expanding economy and increasing standard of living, a continuing interest in the use and properties of traditional herbal medicine (in the literature abbreviated by TCM, i.e., traditional Chinese medicine) demands up-to-date analytical approaches. Typical studies mostly involve a qualitative analytical approach, for example:

1. classical spectral analysis of plant extracts in support of structural proof of isolated constituents
2. quality control of pharmaceutical end products resulting from natural resources

As outlined in the previous paragraph, these studies mostly employ chemometric approaches such as principal component analysis, cluster analysis, and artificial neural networks. In view of the large number of available samples and the complex nature of the samples, quantitative analysis is

Figure 5 Temperature profiles of the CH_2 symmetric stretching vibration in selected phospholipids, showing the gel-to-liquid crystalline phase transition. a, 16:1,16:1-PC; b, 18:1,18:1-PC; c, 14:0,14:0-PC; d, 16:0,16:0-PC.

most frequently carried out using PLS regression of data obtained either by MIR or by NIR spectroscopy. By comparing both spectroscopic methods with chromatographic or other established analytic methods, it appeared that MIR performs slightly better as a result of the better spectral resolution, that is, narrower, well-resolved bands, as compared to the NIR spectral region.

Biomedical and Clinical Applications

Surprisingly, there are no typical zoological infrared spectroscopic applications, but infrared spectroscopy is used in numerous biomedical and clinical chemical studies. Also in the food industry, both MIR and NIR spectroscopy are used with much success and are valued for their high-throughput performance. In the dairy industry, it has been shown that MIR and NIR instruments can be used equally well when replacing classical, time-consuming wet chemical analyses for the determination of fat, protein, and carbohydrate in milk samples. **Figure 7** shows ATR-IR difference spectra of whole milk (**Figure 7a**, solid line) and semiskimmed milk (**Figure 7b**, dotted line) samples. A spectrum of water was subtracted using a factor of 1.00. Protein and carbohydrate content are almost the same as judged from the amide II and carbohydrate bands at 1550 and 1076 cm^{-1} . The lipid content in semiskimmed milk is reduced as shown by the reduced band around 1740 cm^{-1} . Soya milk is strictly not a dairy product but is often used as such. From its spectrum, the reduced fat, protein, and carbohydrate content is easily deduced (**Figure 7c**, dashed

line). Moreover, the carbohydrate composition is different; that is, soya milk does not contain lactose.

Using an ATR probe and an almost completely automated spectrometer, it costs little effort to routinely analyze many liquid samples exhibiting relatively small variations in composition. Yet, often an NIR spectrometer is preferred for dedicated analytic problems in a production environment. In these instances, advantages such as the ruggedness of the instrument, ease of operation, and sampling procedures (immersion probe or through the wall of a vial or container) prevail. These reasons make NIR spectroscopy also very popular in exercise physiology studies in which relative changes in the level of oxygenation of hemoglobin have to be measured *in vivo* and noninvasively. The relatively long pathlengths (typically $1\text{--}2\text{ cm}$) employed in NIR spectroscopy even enables measurements through skin and bone. The measurement of absolute concentrations may impose a problem since pathlengths through the tissue may vary during the measurements as a result of the experimental conditions.

In view of the clinical importance, many investigations of the quantitative analysis of blood serum components have appeared. The six main constituents, that is, total protein, albumin, triglycerides, glucose, urea, and cholesterol, can be simultaneously determined using MIR or NIR spectroscopy and PLS regression. The accuracy meets the criteria that are imposed by accepted clinical chemical methods. Current medical infrared research is aimed at aiding in the diagnosis of certain diseases. It has been shown that rheumatoid arthritis and type I and type

Figure 6 Wavenumber versus temperature plot (FTIR) of the OH stretching vibration band in dried *A. thaliana* *abi3* mutant and wild-type seeds. The data points represent wild-type, *abi3-1*, *abi3-7*, and *abi3-5* seeds. The data of three seeds were averaged. Reprinted from Wolkers WF, Alberda M, Koornneef M, Leon-Kloosterziel KM, and Hoekstra FA (1998) Properties of proteins and the glassy matrix in maturation-defective mutant seeds of *Arabidopsis thaliana*. *The Plant Journal* 16(2): 133–143, with permission from Wiley.

II diabetes can be detected from the infrared spectrum of serum, by comparison with spectra obtained from serum of healthy subjects.

To gain a deeper insight into the functioning of living organisms, many infrared spectroscopic studies are carried out on biochemical systems such as receptors and enzyme systems isolated from animals or humans. Since in most cases the infrared spectrum represents a single, purified protein, the spectrum provides much more detailed structural information. Molecular biology and biochemistry itself provide techniques by which small structural changes can be introduced into these systems:

1. By heterologous expression of the target protein in bacteria or insect cells, the primary structure or amino

acid sequence can be selectively modified using site-directed mutagenesis.

2. Using restricted proteolysis, one may remove or modify certain parts of a protein.
3. Organic synthesis provides strategies for preparing modified receptor ligands.
4. By culturing expression systems on stable isotope-labeled media, the label will be incorporated into the target protein.

In this field, infrared spectroscopy shows itself at its finest, since even minute changes can be detected in an infrared spectrum. When combined with enzymatic activity measurements relative to the unchanged system and, if possible with NMR or X-ray structural data, one

Figure 7 Screening of nutritional components in milk. ATR-IR difference spectra of selected milk samples. A reference spectrum of water is subtracted from the sample spectra. a (solid line), whole milk; b (dotted line), semiskimmed milk. The protein and carbohydrate content approximately equal the levels in whole milk, as judged from the amide II and carbohydrate bands around 1550 and 1076 cm^{-1} , respectively. The lipid content is reduced (weaker $\text{C}=\text{O}$ stretching band around 1740 cm^{-1}). c (dashed line), soya light milk is not a dairy product, but it has a comparable composition. It shows reduced and different sugar composition and reduced protein and lipid content.

Figure 8 Investigating structure–function relationships, using site-directed mutagenesis. By heterologous expression of protein in, for example, *Escherichia coli* bacteria, one can obtain the target protein in high purity and simultaneously have the opportunity to modify its structure by introducing selected mutations. The effect of modifying a single amino acid in a sequence of 133 is readily visible. a, infrared spectrum of muscle fatty acid-binding protein (wild type); b, *Phe*₅₇*Ser*. This position is located at the exterior of the protein. No changes in the spectrum; c, *Phe*₁₆*Ser*. This substitution apparently distorts part of a helical structure around the indicated position since *Ser* is known to induce turn structures; d, *Thr*₄₀*Glu*. Introducing a negative charge in the fatty acid-binding site distorts the β -sheet structure, thereby impairing binding of the ligand.

Figure 9 Effect of isotope labeling on spectral features. a, infrared spectrum of cell line, cultured on conventional growth medium; b, infrared spectrum of cell line, cultured on ^{15}N -enriched medium. By incorporation of ^{15}N into the proteins, the amide II band shows a downshift from 1545 to 1527 cm^{-1} , whereas the amide I band around 1657 cm^{-1} remains at the same position. The overall secondary structure of the proteins remains the same as judged from the conserved amide I band profile and the other spectral features.

can study structure–function relationships to a very detailed level, that is, to that of a single chemical functional group. **Figure 8** gives an impression of the changes in an infrared spectrum, which are the result of substitution of a single amino acid out of 133.

Figure 8(a) shows the spectrum of the native human muscle fatty acid-binding protein, which transports apolar fatty acid molecules through a polar environment. **Figure 8(b)** results from the *Pbe₅₇Ser* mutant, located at the protein exterior. The spectrum is almost equal to 8A, and ligand binding is unchanged. The *Pbe₁₆Ser* substitution shows changes in both amide I and amide II bands (**Figure 8(c)**). This mutant shows an impaired ligand binding. Apparently, the protein structure is changed in such a way that fatty acid binding is inhibited. By the *Thr₄₀Glu* substitution, a negative charge is introduced at the binding site, leading to repulsion of the ligand and a distorted protein structure as deduced from the changes in the amide I and amide II vibrational bands (**Figure 8(d)**). This spectrum even shows the introduction of an additional carboxylate COO^- group, as indicated by the enhanced absorption around 1390 cm^{-1} . In this example, the crystal structure of the native protein obtained from X-ray crystallography supports the interpretation of the spectral changes. In the absence of a crystal structure of the mutant protein, which is difficult to crystallize, infrared spectroscopy can still provide structural information related to the function of the protein.

Since spectra of biological samples inherently consist of many overlapping bands, methods have been developed to

improve the graphical resolution of a spectrum or to disperse the spectral information. Fourier self-deconvolution and calculation of derivative spectra are relatively straightforward spectral manipulation approaches. Multi-dimensional infrared spectroscopic techniques, such as time-resolved FTIR and two-dimensional correlation spectroscopy, spread the spectral information over an extra dimension, that is, time or an additional distance or wavenumber axis. However, these spectral acquisition techniques, are outside the scope of this article. A chemical approach involves the introduction of stable isotope labels, also called isotope editing. By culturing cells on an isotope-enriched medium (e.g., containing ^{15}N or ^{13}C), the label is incorporated into the target protein by biosynthesis. These nonradioactive isotopes do not change the biochemical properties of the protein but introduce well-defined shifts of vibrational bands. Thus, signals of the labeled protein or ligand can easily be distinguished. As an example, **Figure 9** shows the spectrum of a native and a labeled batch of cells, using ^{15}N -enriched culture medium. Unlabeled cells show amide I and amide II bands around 1657 and 1545 cm^{-1} , respectively, whereas in the labeled batch, the amide II band is selectively downshifted toward 1527 cm^{-1} . The amide I remains unchanged.

Most biological macromolecules, including proteins, nucleic acids and carbohydrates, are built of repeating units that are assembled into highly asymmetric structures. The specific conformations of the macromolecules cause the optical transitions of the chromophores in their repeating units (e.g. peptides, nucleotides, glycosides) to align with each other so that their electronic and magnetic transitions interact. The interactions may result in hypo- or hyperchromism and in splitting of the transitions into multiple transitions. In addition, the aligned transitions may exhibit a high degree of circular dichroism (CD) and optical rotatory dispersion (ORD). Because the ORD and CD spectra of macromolecules depend on their conformation, they are excellent probes for following changes in structure as a function of temperature, denaturants or ligand binding. In addition, non-optically active chromophores sometimes bind to macromolecules in highly asymmetric fashions and generate large extrinsic CD and ORD bands in the region of absorption. These extrinsic bands can be used to follow interactions of the macromolecules with the chromophores or to probe structural transitions of the macromolecules. The following article discusses how ORD and CD are used to study the conformation, folding and interactions of proteins, nucleic acids and carbohydrates. Specific examples are given to illustrate each application.

Proteins and Polypeptides

Proteins and polypeptides have two major classes of chromophores, the amide groups of the peptide backbone,

which absorb light in the far-UV (below 250 nm) and the aromatic amino acid side chains and disulfide bonds, which absorb light in both the near (320–250 nm) and far-UV. Far-UV ORD and CD are useful for studying protein structure and folding because many conformations that are common in proteins, including α -helices, β -pleated sheets, poly-L-proline II-like helices and turns, have characteristic spectra. **Figure 1** illustrates representative CD spectra of model polypeptides with different secondary structures. In addition, the chromophores of the aromatic amino acids of proteins are often in asymmetric environments, leading to characteristic CD spectra in the near-UV, which may serve as useful probes of the tertiary structure of proteins.

Analysis of the Secondary Structure of Proteins

Many methods have been developed to extract the conformation of proteins in solution from CD and ORD data. In early studies, the ORD spectra of proteins were analysed to yield structural data, but when commercial CD spectrometers became available in the late 1960s, CD became the method of choice because CD spectra have better resolution than ORD spectra. Basically, all of the analysis methods assume that the spectrum of a protein can be represented by a linear combination of the spectra of the secondary structural elements and a noise term. In constrained fits, the sum of all the fractional weights of each structure must be equal to one. In the first attempts to elucidate protein conformation from CD spectra, the spectra of proteins were fitted by a combination of the spectra of polypeptides with known conformations using the method of least squares (multilinear regression). Once the conformation of many proteins had been determined from X-ray crystallographic analysis, the CD spectra of several well-characterized proteins were deconvoluted into reference (basis) spectra for the α -helix, antiparallel and parallel β -pleated sheets, β -turn and random conformations using multilinear-regression analysis. These extracted curves were then used in place of the polypeptide standard curves. Later, singular-value decomposition (SVD) and convex-constraint analysis (CCA) were used to extract the basis curves. The basis curves obtained from deconvoluting a set of protein CD spectra may vary greatly depending on the choice of reference proteins. This occurs because some proteins have unusual CD spectra in the far-UV, due to aromatic amino acids, disulfide bridges, or rare conformations. To overcome these difficulties, some methods use selection procedures so that only proteins with spectral characteristics that are similar to those of the protein to be evaluated are used as standards. Methods that use selected reference data include ridge-regression, variable-selection and neural-network procedures.

The following computer programs for analysing CD data to yield the secondary structures of proteins and polypeptides are widely available: MLR is a non-constrained and G&F, LINCOMB and ESTIMATE are constrained least-squares-analysis programs; CONTIN uses the ridge-regression technique; VARSLC and SELCON use singular-value decomposition combined with variable selection to compare the structure of unknown proteins with standards; CCA uses the convex-constraint algorithm to deconvolute sets of CD spectra into a minimum number of basis curves and K2D is a neural-network recall program. **Table 1** compares the agreement between the secondary structures of 16 proteins and poly-L-glutamate, determined by analysis of the CD spectra using these computer programs, with the structures determined by X-ray crystallography.

Determination of the Thermodynamics of Protein Folding

The change in the CD spectra as a function of temperature can be used to determine the thermodynamics of unfolding or folding of a protein because the observed change in ellipticity, θ_{obs} , is directly proportional to the change in concentration of native and denatured forms. When the protein is fully folded $\theta_{\text{obs}} = \theta_{\text{F}}$ and when it is fully unfolded $\theta_{\text{obs}} = \theta_{\text{U}}$. For a monomeric protein, the equilibrium constant of folding, $K = \text{folded/unfolded}$. If we define α as the fraction folded at a given temperature, T , then

$$K = \frac{\alpha}{1 - \alpha} \quad [1]$$

$$\Delta G = nRT \ln K \quad [2]$$

where ΔG is the free energy of folding, R is the gas constant and n is the number of molecules.

$$\Delta G = \Delta H(1 - T/T_{\text{M}}) - \Delta C_{\text{p}}[(T_{\text{M}} - T) + T(\ln(T/T_{\text{M}}))] \quad [3]$$

where ΔH is the Van't Hoff enthalpy of folding, T_{M} is the observed midpoint of the thermal transition and ΔC_{p} is the change in heat capacity for the transition. At T_{M} , $K = 1$, therefore $\Delta G = 0$ and $\Delta S = \Delta H/T_{\text{M}}$, where ΔS is the entropy of folding. Rearranging these equations, one obtains

$$K = \exp\left(-\frac{\Delta G}{RT}\right) \quad [4]$$

$$\alpha = \frac{K}{1 + K} \quad [5]$$

$$\theta_{\text{obs}} = (\theta_{\text{F}} - \theta_{\text{U}})\alpha + \theta_{\text{U}} \quad [6]$$

To calculate the values of ΔH and T_{M} that best describe the folding curve, initial values of ΔH , ΔC_{p} , T_{M} , θ_{F} and θ_{U} are estimated, and eqn [6] is fitted to the experimentally observed values of the change in ellipticity as a function of temperature, by a nonlinear least-squares curve-fitting routine such as the Levenberg–Marquardt algorithm. Similar equations can be used to estimate the thermodynamics of folding of proteins and peptides that undergo folded multimer to unfolded monomer transitions.

Figure 2 illustrates how changes in ellipticity as a function of temperature and concentration have been used to determine the enthalpy of folding of a peptide derived from the coiled-coil domain of the yeast GCN4 transcription factor, which undergoes a two-state transition between a folded two-stranded α -helical coiled coil and a monomeric disordered state. The values for the enthalpy of the folding transition, determined from the

^aThe secondary structures of 16 proteins plus poly-L-glutamate were analysed using each computer program as described by Sreerama and Woody (8). *P* is the correlation coefficient between the CD-estimated and X-ray conformations and σ is the mean-square error between the CD-estimated and X-ray conformations. The secondary structures were assigned by the method of Kabsch and Sander (11). When protein databases were used as standards, each protein analysed was excluded from the data set used as the references. When the σ value is higher than the standard deviation (STD) of the mean value of each conformation found in the 17 samples which were analysed, the program does a relatively poor job of analysing that conformation.

^bPGA was excluded from the calculation of *P* and σ because the fit was obviously impossible.

Figure 2 The change in fraction folded of a coiled-coil leucine zipper peptide, GCN4-P1, as a function of temperature and peptide concentration. The concentrations range from 1 μM with the lowest T_M to 20 μM with the highest T_M . The enthalpy of unfolding was $35.0 \pm 1.1 \text{ kcal mol}^{-1}$ (monomer) which compared to that of $34.7 \pm 0.3 \text{ kcal mol}^{-1}$ measured by calorimetry. Abstracted from data in Thompson KS, Vinson CR, and Freire E (1993) *Biochemistry* 32: 5491–5496, with permission from American Chemical Society.

changes in ellipticity as a function of temperature, agree with the values obtained from scanning calorimetry.

In some cases, thermal folding and unfolding studies are impractical. The protein may have a very high T_M or may aggregate and precipitate upon heating. In these cases, denaturants, such as urea or guanidine-HCl, may be added to a protein or peptide to induce unfolding. K , the equilibrium constant of folding, is determined from the ellipticity observed at each concentration of denaturant. It is assumed that the protein is native in the absence of denaturant, and fully unfolded when there is no further change in ellipticity upon addition of higher concentrations of perturbant. At each concentration of denaturant,

$$\alpha = \frac{(\theta_{\text{obs}} - \theta_U)}{(\theta_F - \theta_U)} \quad [7]$$

$$K = \frac{\alpha}{(n[C]^{n-1})(1 - \alpha)^n} \quad [8]$$

α , θ_F and θ_U have the same definitions as in thermal unfolding above, and n is the number of identical subunits. $[C]$ is the total concentration of protein monomers. The free energy of folding is evaluated at every concentration of denaturant using eqn [2] and is plotted as a function of denaturant. The curve is extrapolated to zero denaturant to obtain the free energy of folding of the native material. **Figure 3** depicts the determination of the free energy of folding of a coiled-coil DNA-binding protein from a urea-denaturation study. The peptide forms a two-stranded coiled-coil α -helix when folded and a single-stranded unordered peptide when dissociated.

The association constant and free energy of folding, determined from the denaturation data (**Figures 3b** and **3c**), agree with those determined from the change in ellipticity as a function of peptide concentration (**Figure 3a**).

Analysis of Conformational Transitions

Some native proteins undergo conformational transitions that do not result in formation of a denatured state. Such transitions may involve changes from an α -helical to a β -pleated sheet conformation (or vice versa). Conformational changes of proteins are sometimes followed by oligomerization and aggregation and precipitation reactions that may have important clinical consequences. For example, transitions from a random or α -helical form to a β -sheet may be involved in the pathology of diseases such as scrapie, ‘mad cow disease’ and Alzheimer’s disease. **Figure 4** illustrates how CD has been used to follow the thermal stability and conformational transitions of the scrapie amyloid (prion) protein, PrP27-30. The CD spectra of the solvent-exposed (**Figure 4a**) and re-hydrated solid state PrP27-30, obtained under various conditions, were deconvoluted using the CCA algorithm, and five common spectral components were identified (**Figure 4b**). Infectivity quantitatively correlated with an increasing proportion of a native, β -sheet-like secondary-structure component (**Figure 4c**), a decreasing amount of an α -helical component and an increasingly ordered tertiary structure.

Detection of Folding Intermediates

Often when a protein or peptide folds or unfolds, the process is not a two-state transition between the native and totally disordered forms; intermediate states exist. These states may be transient and may be observed during kinetic measurements of folding or unfolding. Alternatively, they may be stable intermediates, seen when the peptide is subject to denaturing conditions, such as high temperatures, or exposure to urea, guanidine or detergents. These states may be partially folded, with well-defined tertiary structures, or may be so called ‘molten globules’. ‘Molten globule’ is a term describing a compact state with native-like secondary structure but slowly fluctuating tertiary structure. For example, methanol induces the formation of a molten-globule state in the globular protein, cytochrome c. **Figure 5** illustrates the effect of increasing quantities of methanol on the CD spectra of cytochrome c in the near- and far-UV. A loss of ellipticity occurs in the near-UV, that is present in the native state arising from the tertiary interactions of the aromatic chromophores (**Figure 5a**). The far-UV spectra (**Figure 5b**), however, show that the helical content of cytochrome c actually increases upon the

Figure 3 The effects of concentration and urea on the folding of the helix-loop-helix DNA binding domains of the muscle-regulatory DNA transcription factors, MyoD. (a) The change in ellipticity at 222 nm of Myo D as a function of concentration. The data were used to calculate the constant of dimerization $K_{\text{dimer}} = 9.4 \mu\text{M}$. (b) The change in fraction folded of MyoD as a function of urea concentration. (c) ΔG of folding calculated from the data in (b). The extrapolated free energy of folding calculated from the value at 0 urea was similar to those calculated from the dimerization constant. addition of methanol, as shown by the increasing ellipticity at 222 and 208 nm.

Determination of the kinetics of protein folding

Besides the study of protein folding under equilibrium conditions, CD can be used to measure rapid events in protein folding and unfolding by attaching a rapid mixing device to a CD spectropolarimeter. Stopped-flow CD can be used both to obtain the kinetic constants of folding reactions and to define the conformation of folding intermediates. Data can be collected in the far- and near-UV. The far-UV data give information about the secondary structure of the protein, while the near-UV data are windows that monitor the formation of tertiary structure.

Stopped-flow CD studies of highly helical two-stranded coiled coils and four-helix bundle proteins have

shown them to fold in essentially two-state transitions. The kinetics of folding of globular proteins, however, can be very complex. For example, the kinetics of the unfolding and refolding of bovine β -lactoglobulin, a predominantly β -sheet protein in the native state, are illustrated in **Figure 6**. The kinetics of unfolding (**Figures 6a** and **6b**) show a single-phase transition between the folded and denatured form, with the loss of secondary structure (**Figure 6a**) and tertiary structure (**Figure 6b**) being simultaneous. The refolding reaction, in contrast, is a complex process composed of different kinetic phases (**Figure 6c**). In particular, a burst-phase intermediate is formed during the dead time of stopped-flow measurements that shows more intense ellipticity signals in the far-UV than does the native state. This more intense CD is due to the transient formation of a nonnative α -helical structure (**Figure 6d**). The CD spectrum suggests the folding intermediate exists in a

Figure 4 (a) Solvent-induced conformational transition of PrP27-30 scrapie amyloid (prion) protein in the solid state on quartz glass. Films were exposed for 20–30 min to SDS, sodium dodecyl sulfate; TFE, trifluoroethanol; HFIP, hexafluoroisopropanol; TFA, trifluoroacetic acid; FA, 99% formic acid. “f” is the spectrum with no treatment at 23 °C. (b) Data on PrP27-30 obtained under various conditions, deconvoluted into five basis curves using the convex-constraint algorithm. (—) β -turn type I or III and 3_{10} -type helix; (·····) α -helix; (-----) β -sheet; (- - -) β -turn type II; (- · - ·) additional chiral contribution. (c) Correlation of the solvent-induced changes in the β -sheet component with infectivity. The data for dehydrated films are open circles and rehydrated films are closed circles. The data obtained with TFA and FA, where the proteins were highly helical and the infectivity was very low, are excluded from the fits. (o) dehydrated films (▲) rehydrated films. molten globule state, since there are no near-UV CD bands indicative of tertiary structure. Similarly, intermediate states have been shown to exist in the refolding of diverse proteins including cytochrome c, ribonuclease HI from *E. coli*, dihydrofolate reductase, alcohol dehydrogenase, carbonic anhydrase, retinoic acid-binding protein and staphylococcal nuclease.

Analysis of Protein–Ligand Interactions

Circular dichroism can be used to follow the binding of ligands to proteins, peptides, nucleic acids and carbohydrates provided one of two criteria is fulfilled. Either the ligand must bind in an asymmetric fashion that induces *extrinsic* optical activity in the chromophores of the

bound ligand or the binding must result in a conformational change in the macromolecule that results in a change in its *intrinsic* CD spectrum. In the case of equivalent binding sites, the change in ellipticity due to complex formation is directly proportional to how much ligand is bound. Thus, the change in ellipticity as a function of substrate concentration can be used to estimate the binding constants.

Extrinsic ellipticity bands (called Cotton effects), developed when chromophores bind to proteins, have been used to study protein–ligand interactions in many diverse systems. **Figure 7a** illustrates the induction of extrinsic CD bands when retinol binds to interphotoreceptor retinol-binding protein, and **Figure 7b** shows the change in the ellipticity at the wavelength of

Figure 5 (a) Near-UV CD and (b) Far-UV CD spectra of cytochrome c (pH 4.0 in 0.5 M NaCl, 24°C) at methanol concentrations shown near the curves. The negative bands in the near-UV spectrum are attributed to the side chain of the single Trp59 residue. They decrease and almost vanish at methanol concentration > 40%. Abstracted from data in Bychkova VE, Dujsekina AE, Klenin SI, Elisaveta IT, Uversky VN, and Ptitsyn OB (1996) *Biochemistry* 35: 6058–6063, with permission from American Chemical Society.

maximal ellipticity as a function of ligand concentration. Extrinsic Cotton effects have been used to study the binding of many other cofactors to proteins, including the binding of nucleotides to lactic dehydrogenase, folates and antimetabolites to dihydrofolate reductase, ATP to GroEL and pyridoxal phosphate to tryptophan synthase. They have also been used to study the interactions of substrates with enzymes including tryptophan synthase and *N*-acetylglucosamyl transferase, to study the interactions of drugs with bovine serum albumin and to examine the interactions of DNA, binding proteins with DNA.

The binding of ligands to proteins often results in conformational transitions. The resultant change in the intrinsic ellipticity of the backbone amides caused by the conformational change can be used to obtain the ligand-binding constants. For example, divalent cations are effectors in many biological systems, and their binding often induces large conformational changes in the target protein. Calcium-ion binding to calmodulin and troponin C induces an increase in the ellipticity of the proteins due to stabilization of α -helical regions. Many other broad classes of protein-ligand interactions result in conformational changes. For example, DNA binding to

Figure 6 (a) Unfolding curve of β -lactoglobulin (β -LGA) measured by the CD changes at 293 nm at pH 3.2 at 4.5°C. The change was initiated by jumping the guanidine HCl (GdnHCl) concentration from 0 to 4.0 M. The vertical arrows show the change in ellipticity in $\text{deg}\cdot\text{cm}^2\cdot\text{dmol}^{-1}$ (b) Same, measured at 220 nm. (c) Kinetic refolding curve of β -LGA measured by the CD change at 221 nm. Refolding was initiated by dropping the concentration of GdnHCl from 4 to 0.4 M. (d) CD spectrum of β -LGA in the far-UV at pH 3.2 and 4.5°C. (—) native state; (----) unfolded state in 4 M GdnHCl; (- - -) disulfide-cleaved and carboxymethylated material in 4 M GdnHCl; (○) ellipticity of β -LGA at 0 time after refolding; (●) ellipticity of β -LGA at 255 min after refolding. many different DNA transcription factors results in increases in the helical content of the factors. These DNA binding proteins often contain α -helical-coiled-coil or helix-loop-helix motifs, which serve as dimerization domains, and a relatively unstructured basic region which binds to the DNA. Upon DNA binding the basic region assumes a helical conformation.

Nucleic Acids

Nucleic acids are polymers of nucleotides that consist of purine or pyrimidine bases attached to a phosphorylated sugar. Monomeric sugars are asymmetric, and they induce a small amount of ellipticity in the attached planar-symmetric base. Polymerized nucleic acids, however, are rigid and highly asymmetric. In the polymerized nucleic acids, the bases stack with one another in precise orientations depending on the conformational state. Base

stacking leads to characteristic splittings of the transitions of chromophores of the bases into multiple transitions, and the rigidity leads to CD bands with high rotational strength. CD spectra of polynucleotides are sensitive both to their sequence and conformation, and can provide a good deal of structural information.

Analysis of the Secondary Structure of Polynucleotides

Homopolynucleotides

Even very simple polynucleotides show multiple conformational states and complex CD and ORD spectra. Compounds as small as homodimers of ribo and deoxyribonucleotides show evidence of base stacking in solution from measurements of optical activity. For example, **Figure 8a** illustrates the circular dichroism properties of several riboadenylate compounds. AMP shows a single absorption band and a single negative CD

Figure 7 (a) Near-UV mean-residue circular-dichroism ellipticity, $[\theta]$, in $\text{deg.cm}^2.\text{dmol}^{-1}$, of interphotoreceptor retinol-binding protein (IRBP), $0.4\text{--}0.8\text{ mg ml}^{-1}$, with and without bound retinol. (b) Circular-dichroism titration curve of apo-IRBP, 0.4 mg ml^{-1} , with retinol. The height of the extrinsic Cotton effect at 330 nm is calculated in ellipticity per mole of IRBP. Redrawn from data in Adler AJ, Evans CD, and Stafford WF (1985) *Journal of Biological Chemistry* 260: 4850–4855, with permission from The American Society for Biochemistry & Molecular Biology.

band at 260 nm . Diadenylic acid has a single UV band at 260 nm , but a split CD spectrum with a positive band at 270 nm and a negative band at 250 nm . Theoretical calculations of the CD spectrum agree with a model where the bases are stacked in a parallel fashion in the dinucleotide. The stacking leads to hypochromicity in the absorption spectrum, and splitting of the transitions into two transitions, one perpendicular and one parallel to the helix axis with equal strength and opposite rotatory strength. Poly(rA) has a spectrum similar to that of diadenylate but higher in magnitude.

The CD spectrum of poly(rA) changes with pH, chain length and temperature. At neutral pH, poly(rA) is unprotonated and forms a single-stranded helix. At acidic pH, poly(rA) forms dimers. Depending on the pH there are two conformational forms, one where poly(rA) is fully protonated, and one where it is half-protonated. **Figure 8b**

shows the chain-length dependence and **Figure 8c** the temperature dependence of the rotational strength of the positive-ellipticity band of the single-stranded form at pH 7.4 and the double-stranded half-protonated form at pH 4.5. Both the chain-length dependence and the unfolding of the double-stranded forms as a function of temperature are more cooperative than that of the single-stranded form.

Heteropolynucleotides

Circular dichroism spectra of nucleic acids are complex, compared to those of homopolynucleotides because four different bases contribute to the CD spectra, and the spectra are sequence dependent. In addition, nucleic acids display great conformational diversity and may form single-, double- or triple-stranded helices. For example, the spectra of poly(rA), poly(rU), the dimer poly(rA) · poly(rU) and the trimer poly(rU) · poly(rA) · poly(rU) are illustrated in **Figure 9**. Complex formation results in shifts in wavelength and intensity of the bands compared to the addition of the spectra of the unmixed components.

The various oligomerization states of the polynucleotides, moreover, can exist in multiple conformations. For example the A, B and Z forms of double-stranded nucleic acids have distinct CD spectra. **Figure 10a** illustrates the CD spectra of poly(dAdC) · poly(dGdT) in the A, B and Z conformations, and **Figure 10b** illustrates CD spectra of a double-helical polynucleotide, poly(dGdC) · poly(dGdC) in the B form, the Z form and in a form in which the bases assume the Hoogsteen base-pairing conformation.

Analysis of Conformational Transitions of Nucleic Acids

Conformational transitions of nucleic acids can be followed by examining CD and ORD spectra as a function of temperature and denaturants, and the thermodynamic parameters of the transitions can be determined using the same equations used to determine the thermodynamics of folding of proteins. In addition, the spectra of nucleic acids, obtained under varying conditions, can be deconvoluted using the CCA and SVD methods to determine whether there are folding intermediates, as in the case of proteins.

Analysis of Ligand Binding to Nucleic Acids

Circular dichroism and ORD are excellent methods to follow the binding of ligands to nucleic acids. The same equations that are used to analyse protein–ligand interactions may be applied to the study of DNA–ligand interactions. For example, CD and ORD have been used to examine the binding of DNA to proteins, drugs and amines. **Figure 11** illustrates the effect of binding of

spermidine to poly(dT) · poly(dA) · poly(dT). The addition of the amine has dramatic stabilizing effects. The conformation of the polynucleotide complex undergoes sequential changes from B-DNA to triplex DNA as the concentration of spermidine is increased from 0 to 50 μM . At 60 μM spermidine, the CD spectrum of triplex DNA is comparable to that of ψ -DNA, with a strong positive band centred around 260 nm. A negative band is also found at 295 nm. At higher concentrations of spermidine, however, the intensity of the positive band progressively decreases. The peak intensity is found at a 1:0.3 molar ratio of DNA phosphate-spermidine.

Figure 12 illustrates an example of DNA-protein binding study. The gene 32-coded protein of bacteriophage T4 is necessary for genetic recombination and DNA replication. It denatures poly(dAdT) · poly(dAdT) and T4 DNA at temperatures far below their regular melting temperatures. The protein interacts with native DNA and a variety of synthetic polynucleotides. Illustrated here is

the interaction of the protein with poly(dA). The CD spectra suggest that the protein keeps poly(dA) in a conformation that is equivalent to that of a single-stranded form in high salt. Similar results were obtained with other dimeric DNA analogues including poly(dA) · poly(dT) and poly(dT).

Carbohydrates

Carbohydrates are much more difficult to study using ORD and CD than proteins and nucleic acids and much less literature is available. First, carbohydrates mainly absorb below 190 nm, a region difficult to examine using commercial CD spectrometers. Second, unlike proteins and nucleic acids, there are no common sets of spectral characteristics which easily define the conformation of carbohydrates. However, ORD and CD have been used to obtain useful information about the structure of

carbohydrates. In favourable circumstances, they can give information about the structure and linkages in carbohydrates. In addition, they can distinguish helical from disordered conformations and be used to monitor

conformational transitions induced by salts, solvents and temperature.

Determination of Carbohydrate Structure and Linkages

While no simple basis spectra exist that can be used to determine the conformation of carbohydrates, analysis of the CD spectra of monomeric carbohydrates has provided empirical rules for extracting some conformational information. By comparing the spectra of monomeric sugars, researchers have been able to assign the CD bands to specific transitions and to determine quadrant rules for the effect of structure on the sign of the transitions. For example, the CD spectra of methyl- β -galactopyranoside, carrageenan and agarose are shown in **Figure 13**. X-ray films of carrageenan show that the conformation is a double helix. The CD spectrum of carrageenan is consistent with the conformation seen in the X-ray analysis. There are conflicting models for the structure of agarose in gels. In one model the chains are extended and in the other they are helical. The geometry-dependent linkage contributions to the CD of agarose were determined by subtracting the monomeric CD from the CD of the polymer. Application of the quadrant rules indicated that agarose was also helical. The difference in CD sign between carrageenan and agarose arises from a translocation of the β -D-galactose O-2 atom from one quadrant to the neighbouring quadrant of the C-5-O-5-C-1 ether chromophore of the preceding anhydro sugar residue.

CD and ORD serve as simple methods for following order–disorder transitions in carbohydrates. Because the absorption bands of carbohydrates are at very low wavelength, many of the studies of conformational transitions have been done using ORD, since ORD bands extend even into the visible region and are more easily accessible. For example, **Figure 14** shows how the effects of potassium ion concentration and temperature on the order–disorder transition of xanthan, an extracellular polysaccharide produced by *Xanthomonas campestris*, have been followed by measuring the optical rotation at 365 nm. The data were used to find the enthalpy of folding of the polymer. The data could also be fitted by Zimm–Bragg helix–coil transition analysis. Similar studies of conformational transitions have been performed on other carbohydrates including acetan, carrageenan, succinoglycan and hyaluronate.

In addition to monitoring the folding of carbohydrates by examining changes in the intrinsic optical activity of the carbohydrate, structural information has been obtained by examining the CD and ORD spectra of bound dyes. For example when methylene blue binds to carrageenan, the binding induces optical activity in the dye which changes as a function of temperature. There is a progressive loss of ellipticity as a function of temperature, suggesting that the dye binds to the double-helical form of the polysaccharide but not the coil form.

Symbols

A	absorbance
$c_{b,f}$	ligand concentration
I	transmitted light intensity
I_0	incident light intensity
l	sample light path length
ϵ	molar absorption coefficient
λ	wavelength of radiation (usually in nm)
ν	frequency of radiation (s^{-1})

Introduction

Ultraviolet (UV) or visible radiation is absorbed by a molecule when the frequency of light is at correct energy to cause the electrons of the molecule to rearrange (or become excited) to another higher-energy state of the system. Frequency, ν (measured in s^{-1}), wavelength, λ (usually measured in nm), and energy, E (measured in J), are related by

$$E = h\nu = \frac{hc}{\lambda}$$

where $h = 6.626\,196 \times 10^{-34} \text{ J s}$ is the Planck constant and $c = 2.997\,925 \times 10^{17} \text{ nm s}^{-1}$ is the speed of light in units to match the choice of nm for λ .

Absorption can be pictorially viewed as either the electric field or the magnetic field (or both) of the radiation pushing the electron density from a starting arrangement to a higher-energy final one. The direction of net linear displacement of charge is known as the polarization of the transition. The polarization and intensity of a transition are characterized by the so-called transition moment, which is a vectorial property having a well-defined direction (the transition polarization) within each molecule and a well-defined length (which is proportional to the square root of the absorbance). The transition moment may be regarded as an antenna by which the molecule absorbs light. Each transition thus has its own antenna and the maximum probability of absorbing light is obtained when the antenna and the electric field of the light are parallel.

Absorbance is defined in terms of the intensity of incident, I_0 , and transmitted, I , light

$$A = \log_{10} \left| \frac{I_0}{I} \right|$$

In most experiments the Beer–Lambert law used to relate the absorption of light, A , to the sample concentration, C

$$A = \epsilon Cl$$

where l is the length of the sample through which the light passes and ϵ is the molar absorption coefficient (extinction coefficient); if l is measured in cm and C in $M = \text{mol dm}^{-3}$, then ϵ has units of $\text{mol}^{-1} \text{ dm}^3 \text{ cm}^{-1}$. The Beer–Lambert law breaks down when the sample absorbs too high a percentage of the incident photons for the instrument to measure the emitted photons. An absorbance of 2, for example, means that 99% of the photons are absorbed. Biological samples present additional challenges to the Beer–Lambert law: If there are local high concentrations of sample (as in vesicles for example) or if molecules interact and perturb the spectroscopy of the isolated molecule, then the Beer–Lambert law becomes invalid.

The most common application of UV-visible absorption spectroscopy is to determine the concentration of a species in solution using the Beer–Lambert law. Other applications follow because the energy of UV-visible light is usually sufficient only to excite valence electrons that are the ones involved in bonding. Thus any UV-visible absorption spectrum is directly related to bonds and hence the structure of a molecule. The challenge is then to relate the plot of absorbance versus wavelength, which the spectrometer produces, to the structure of the molecules in the cuvette. With complicated systems, such as biological macromolecules and their complexes with small molecules, UV-visible spectra are usually interpreted by considering changes in the spectrum as a function of a variable such as temperature, ionic strength, solvent, concentration, etc. Alternatively the absorption spectra data are used as input for interpreting other spectra such as fluorescence, circular dichroism (CD), or linear dichroism (LD).

Biological Macromolecule Structure and UV Spectroscopy

Proteins and DNAs are linear polymers where a limited set of residues are joined together by, respectively, the amide or phosphodiester bonds. The situation is similar for carbohydrates though the linking options are more varied.

To a first approximation, the absorbance spectrum expected for a biomolecule is therefore the sum of the spectra for the component parts.

In the case of nucleic acids (DNA and RNA), the UV absorbance from 200–300 nm is due exclusively to transitions of the planar purine and pyrimidine bases (**Figure 1**). (The backbone begins to contribute at approximately 190 nm.) The accessible region of the spectrum (nitrogen purging is required below ~ 200 nm as oxygen absorption interferes with the spectrum) is therefore dominated by $\pi \rightarrow \pi^*$ transitions of the bases. The UV spectra of the bases (**Figure 2**) look as if there are two simple bands; however, each ‘simple’ band observed is a composite of more than one transition. This makes detailed analysis of DNA absorption difficult, but usually ensures that the absorption spectrum changes when the system is perturbed. Thus absorption spectroscopy is a useful qualitative or empirical probe of structural changes. Typical DNA UV absorption spectra are illustrated in **Figure 3**. The base transitions are significantly perturbed by the so-called π – π stacking interactions and so both wavelength maxima and transition intensities vary depending on the base sequence and structure adopted (cf. **Table 1**).

In the case of peptides and proteins, the spectroscopy of the amide bonds, the side chains and any prosthetic groups (such as haems) determines the observed UV-visible absorption spectrum. However, as with DNA, intensities and wavelengths can be perturbed by the local

environment of the groups. UV spectra of proteins are usually divided into the ‘near’ and ‘far’ UV regions. The near-UV in this context means 250–300 nm and is

Figure 2 UV spectra of the DNA nucleotides: deoxyadenosine 5'-monophosphate (A), deoxyguanosine 5'-monophosphate (G), deoxycytidine 5'-monophosphate (C) and thymidine 5'-monophosphate (T). The spectrum of uracil is almost indistinguishable from that of thymine.

Figure 3 Absorbance spectra in 1 cm pathlength cuvettes of 190 μ M poly[d(G-C)]₂ (dotted line) and 240 μ M poly[d(A-T)]₂ (dashed line).

Figure 1 Structural formula of DNA.

Table 1 Long-wavelength absorbance maxima and extinction coefficients for some DNAs. Calf thymus DNA is $\sim 60\%$ A-T

DNA	Wavelength of $A_{\max}(\text{nm})$	$\epsilon_{\max}$ ($\text{mol}^{-1} \text{ dm}^3 \text{ cm}^{-1}$)
Calf thymus	260	6 600
Poly[d(A-T)] ₂	262	6 600
Poly(dA) · poly(dT)	260	6 000
Poly[d(G-C)] ₂	254	8 400
Poly(dG) · poly(dC)	253	7 400

(A = adenine, T = thymine, G = guanine and C = cytosine)

also described as the aromatic region, though transitions of disulfide bonds (cystines) also contribute to the total absorption intensity in this region. The far-UV (<250 nm) is dominated by transitions of the peptide backbone of the protein, but transitions from some side chains also contribute to the spectrum below 250 nm.

The aromatic side chains, phenylalanine, tyrosine and tryptophan all have transitions in the near-UV region (Figure 4). At neutral pH, the indole of tryptophan has two or more transitions in the 240–290 nm region with total maximum extinction coefficient $\epsilon_{\max}(279 \text{ nm}) \sim 5000 \text{ mol}^{-1} \text{ dm}^3 \text{ cm}^{-1}$; tyrosine has one transition with $\epsilon_{\max}(274 \text{ nm}) \sim 1400 \text{ mol}^{-1} \text{ dm}^3 \text{ cm}^{-1}$; phenylalanine also has one transition with $\epsilon_{\max} \sim 190 \text{ mol}^{-1} \text{ dm}^3 \text{ cm}^{-1}$; and a cystine disulfide bond absorbs from 250–270 nm with $\epsilon_{\max} \sim 300 \text{ mol}^{-1} \text{ dm}^3 \text{ cm}^{-1}$. Although tryptophans have by far the most intense transitions, many proteins have few tryptophans compared with the other aromatic groups, so the near UV is not necessarily dominated by tryptophan transitions.

Figure 4 Aromatic absorption spectra of tryptophan, tyrosine and phenylalanine. Note the different concentrations required to ensure absorbance maxima of 1 absorbance unit.

The peptide chromophore (Figure 5) which gives rise to the transitions observed in the far-UV region (180–240 nm) has nonbonding electrons on the oxygen and also on the nitrogen atoms, π -electrons which are delocalized to some extent over the carbon, oxygen and nitrogen atoms, and σ bonding electrons. The lowest energy transition of the peptide chromophore is an $n \rightarrow \pi^*$ transition analogous to that in ketones, and the next transition is $\pi \rightarrow \pi^*$. As in the carbonyl case, the $n \rightarrow \pi^*$ transition is predominantly of magnetic transition dipole character and is thus of low intensity ($\epsilon \sim 100 \text{ mol}^{-1} \text{ dm}^3 \text{ cm}^{-1}$), though it is not as low as for a simple ketone; it occurs at approximately 210–230 nm (depending mainly upon the extent of hydrogen bonding of the oxygen lone pairs) and its small electric character is polarized more or less along the carbonyl bond. The $\pi \rightarrow \pi^*$ transition ($\epsilon \sim 7000 \text{ mol}^{-1} \text{ dm}^3 \text{ cm}^{-1}$) is dominated by the carbonyl π -bond and is also affected by the involvement of the nitrogen in the π orbitals; its electric dipole transition moment is polarized somewhere near the line between the oxygen and nitrogen atoms, and it is centred at 190 nm.

In an α -helix, the coupling of the $\pi \rightarrow \pi^*$ transition moments in each amide chromophore results in a component at approximately 208 nm which contributes to the characteristic α -helix CD spectrum. For UV-visible spectroscopy, however, the far-UV spectroscopy is usually of little use either for concentration determination or structural analysis as the accessible region (above 200 nm) is almost a linear plot of increasing intensity with decreasing wavelength.

Carbohydrate UV-visible spectroscopy is essentially that of any substituents that have chromophores; a simple sugar system such as starch has no absorption above 200 nm. Carbohydrates are typically derivatized with thiols or aromatic chromophores for UV spectroscopy. The spectroscopy of these compounds is largely determined by that of the derivatives. These data may be found in UV-visible spectroscopy atlases.

Figure 5 Schematic illustrations of (a) $n \rightarrow \pi^*$ and (b) $\pi \rightarrow \pi^*$ transitions of peptides.

Wavelength Scanning

Simple Wavelength Scans of Biological Macromolecules

Nucleic acids (DNA and RNA), proteins and peptides absorb very little light above 300 nm in the absence of ligands or prosthetic groups with chromophores (absorbing units). However, it is usually wise to collect a simple UV scan of a sample from approximately 350 nm. If the spectrum is not flat between 350 and 310 nm, then the sample has condensed into particles whose size is of the order of the wavelength of light; therefore what is being observed is scattering of the incident light rather than absorption. UV absorbance is most commonly used to determine the concentration of a sample and also to give an indication of its purity.

To perform a wavelength scan, proceed as follows:

1. First choose the parameters.

The wavelength range will usually be 350–200 nm, unless the buffer cuts out the low-wavelength end (see next point).

A data interval of 0.5–1 nm is adequate as the bands are all broad. Shorter data intervals will not improve the plotted spectrum but will fill up the computer memory. (If data is being collected to aid interpretation of LD spectra, ensure that the data interval is the same in both cases.)

The bandwidth is the wavelength range of the radiation at any specified wavelength. If data is being collected every 0.5 nm, then a bandwidth of 0.5 nm is appropriate. A larger value will lead to a greater averaging of data than the data interval suggests. Do not choose a very small bandwidth as the incident light intensity will be reduced and the spectral noise will increase without improving the quality of the data.

The data averaging time determines the signal-to-noise ratio and affects the scan speed required to produce undistorted spectra. A time range of 0.033–0.1 s is usually a good choice; longer times are required if the absorbance is very small (less than 0.1 absorbance units) or small differences in absorbance are being determined (as for DNA melting curves; see section on DNA melting curves).

2. Choose the solvent or buffer for the experiment and fill a pair of matched cuvettes of the desired pathlength with it. Either switch off the baseline correction or use an air/air baseline in the instrument. Place one cuvette in the sample holder (usually the front position) and leave the reference holder empty. Run a spectrum over the desired wavelength range to check that the solvent/buffer spectrum is not significant over the wavelength range of interest. If it is, change the solvent/buffer.

In choosing the buffer note phosphate buffers are essentially spectroscopically invisible over the wavelength

range usually used; however, it is necessary to ensure that phosphate does not interact in any way with the sample. Cacodylate and ammonium acetate have a window down to ~210 nm and have the added advantage of preventing bacterial growth (whereas phosphate promotes it). Chloride ions begin absorbing just above 200 nm so high salt spectra cannot be collected at the lower-wavelength end of the spectrum. Higher buffer concentrations can be accommodated in shorter pathlength cuvettes (see Beer–Lambert law discussion in the Introduction section), so if it is not possible to dilute or change the buffer try a smaller pathlength cuvette. (5 mm cuvettes will stand in a normal sample holder, 1 mm cuvettes will need spacers to hold them vertical – if they are not held vertical then a variable path length will result. Smaller pathlength cuvettes will need special holders.) UV cut-off wavelengths for solvents are readily available in liquid chromatography texts.

3. Place the matched solvent/buffer cuvettes in both the reference holder (usually the rear position) and the sample holder and perform a baseline accumulation. An alternative to having the solvent/buffer in the reference beam is to use a reference cell of water and collect a spectrum of the solvent/buffer which is subsequently subtracted from all spectra. This method may be preferable if the solvent/buffer has a significant absorbance as it is easier to determine whether an apparent peak or dip in the spectrum is due to the buffer in some way.
4. Place the sample in the sample cuvette in the sample holder and record the spectrum.

The absorbance at ~260 nm (or wherever the maximum is for a particular molecule) is generally used to determine nucleic acid concentrations using the Beer–Lambert law. As noted above, for DNA samples the linear relationship between concentration and absorbance seems to break down when the absorbance of a 1 cm pathlength solution exceeds ~1.5–2 absorbance units. Some DNA extinction coefficients are given in Table 1.

Protein absorbances will be dominated by tryptophan residues (if there are any) and will have a maximum at 280 nm. The other aromatic residues also absorb at 280 nm. Absorbance at 280 nm may therefore be used to give an estimate of protein concentrations. At 280 nm a 1 mg cm⁻³ protein solution in a 1 cm pathlength cell often has an absorbance of ~1 absorbance unit. This is because many proteins have a similar percentage of 'aromatic' amino acid residues. However, the A_{280} (1 mg cm⁻³) can vary from 0.3 to 1.8. For example, the A_{280} (1 mg cm⁻³) for bovine serum albumin is ~0.66. In cases where the protein amino acid content and molecular weight are known, a reasonably accurate estimate of ϵ can be made using the above ϵ values for the residues

(instead of assuming $A_{280} = 1$ for 1 mg cm^{-3}) and then the Beer–Lambert law applied.

The Beer–Lambert method for concentration determination of nucleic acids and proteins is based on the assumption that the samples are pure. Nucleic acids, if present, will interfere with the protein concentration determination because they also absorb at 280 nm, and conversely. In these cases the following formula permits a rough estimate of protein concentration in the presence of nucleic acids (for a 1 cm pathlength cuvette):

$$1.55 \times A_{280} - 0.76 \times A_{260} = \text{mg protein cm}^{-3}$$

It is also common practice to report the A_{280}/A_{260} ratio as an indication of purity for a given sample.

Wavelength Scans of Derivatized Protein Samples for Concentration Determination

Although proteins have different percentages of the different amino acids, each residue has an amide bond linking it to the next residue in the chain. A number of concentration-determination methods have thus been developed that involve derivatizing the amides and spectroscopically determining the concentration of the derivatives. The three methods mentioned below all rely on a standard of known concentration to enable a calibration curve to be plotted. The calibration is not necessarily linear.

Biuret method

This method is simple and reasonably specific as it depends on the reaction of copper(II) with four N atoms in the peptide bonds of proteins. Compounds containing peptide bonds give a characteristic purple colour when treated in alkaline solution with copper sulfate. This is termed the ‘biuret’ reaction because it is also given by the substance biuret $\text{NH}_2\text{CONHCONH}_2$. For a wide variety of proteins, 1.0 mg of protein in 2 cm^3 of solution results in an absorbance at 540 nm of 0.1. Many haemoproteins, for example, give spurious results due to their intrinsic absorption at 540 nm, but modifications which overcome this difficulty are known (either removal of the haem before protein estimation or destruction of the haem by hydrogen peroxide treatment). The protein content of cell fractions such as nuclei and microsomes can be estimated by this method after solubilization by detergents such as deoxycholate or sodium dodecyl sulfate.

The biuret reagent may be made by placing $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ (1.5 g) and sodium potassium tartrate $\cdot 4\text{H}_2\text{O}$ (6.0 g) into a dry 1 dm^3 volumetric flask and adding approximately 500 cm^3 of water. With constant swirling, NaOH solution (300 cm^3 , 10% w/v) is added and the solution made to volume (1 dm^3) with water. The reagent prepared in this manner is a deep blue colour. It may be stored indefinitely if KI (1 g) is also added and the

reagent is kept in a plastic container. The protein solution ($x \text{ cm}^3$, where $x < 1.5$) is then mixed with water $[(1.5 - x) \text{ cm}^3]$ to make a total volume of 1.5 cm^3 to which 1.5 cm^3 of biuret reagent is added. The purple colour is developed by incubating for 20 min at 37°C . The tubes must then be cooled rapidly to room temperature and the absorbance at 540 nm determined. The colour of the solution is stable for hours.

Folin–Ciocalteu or Lowry method

While the biuret method is sensitive in the range 0.5 to 2.5 mg protein per assay, the Lowry method is 1 to 2 orders of magnitude more sensitive (5 to 150 μg). The main disadvantage of the Lowry method is the number of interfering substances; these include ammonium sulfate, thiol reagents, sucrose, EDTA, Tris, and Triton X-100.

The final colour in the Lowry method is a result of two reactions. The first is a small contribution from the biuret reaction of protein with copper ions in alkali solution. The second results from peptide-bound copper ions facilitating the reduction of the phosphomolybdic acid (the Folin reagent) which gives rise to a number of reduced species with a characteristic blue colour. The amino acid residues which are involved in the reaction are tryptophan and tyrosine as well as cysteine, cystine and histidine. The amount of colour produced varies slightly with different proteins. In this respect it is a less reliable assay than the biuret method, but it is more reliable than the absorbance method since A_{280} may include contribution from other species, and also the absorption of a given residue is dependent on its environment within the protein.

Two solutions are required for the Lowry method. For the alkaline copper solution, mix 50 cm^3 Na_2CO_3 (2% w/v) in NaOH (0.1 M) with 1 cm^3 of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ (0.5% w/v) and 1 cm^3 of sodium potassium tartrate (1% w/v). This solution must be discarded after 1 day. The Folin reagent (phosphomolybdic acid) may be made by diluting the concentrated Folin reagent obtained from, for example Sigma with an equal volume of water so that it is 1 N (i.e. 1 M H^+).

To perform an assay add $x \text{ cm}^3$ of sample (where $x < 0.6$) containing 5–100 μg of protein as required to $(0.6 - x) \text{ cm}^3$ of water. Then add 3 cm^3 of the alkaline copper solution. The solutions must then be mixed well and allowed to stand for 10 min at room temperature. Add 3.0 cm^3 of Folin reagent and after 30 min, determine the absorbance at 600 nm.

Coomassie blue dye binding assay

This protein-determination method involves the binding of Coomassie brilliant blue G-250 to protein. The protonated form of Coomassie blue is a pale orange-red colour whereas the unprotonated form (Figure 6) is blue. When proteins bind to Coomassie blue in acid solution

Figure 6 Coomassie blue.

their positive charges suppress the protonation and a blue colour results. The binding of the dye to a protein causes a shift in the absorption maximum of the dye from 465 to 595 nm and it is the increase in absorbance at 595 nm that is monitored. The assay is very reproducible and rapid with the dye-binding process virtually complete in ~ 2 min with good colour stability.

The reagent is prepared as follows. Coomassie brilliant blue G-250 (100 mg) is dissolved in 50 cm³ 95% ethanol. To this solution phosphoric acid (100 cm³, 85% w/v) is added and the solution diluted to 1 dm³. To perform the assay, x cm³ of the sample containing 5–100 μ g of protein is placed in a clean, dry test tube. Water, (0.5– x) cm³, and 5.0 cm³ of diluted dye reagent are added and the solution mixed well. After a period of 5–60 min, A_{595} is determined.

The only compounds found to give excess interfering colour in the assay are relatively large amounts of detergents such as sodium dodecyl sulfate, Triton X-100 and commercial glassware detergents. Interference by small amounts of detergent may be eliminated by the use of proper controls. The assay is nonlinear and requires a standard curve.

Simple Wavelength Scans of Macromolecules with Bound Ligands

When a ligand is added to, for example, a DNA solution, if it does not bind to the DNA then the UV-visible spectrum will simply be the sum of the DNA spectrum and the ligand spectrum. If the ligand binds to the DNA then the spectrum of the complex will be different from the sum spectrum. One should note that the observed spectrum is probably a complicated mixture of that due to bound and unbound ligand and free and complexed DNA.

When a planar aromatic molecule binds intercalatively (sandwiched between two base pairs) to DNA there is usually a characteristic decrease in the ligand-absorbance

Figure 7 (a) 5 μ M anthracene-9-carbonyl- N^1 -spermine in water. (b) 2 μ M, 4 μ M, 5 μ M, 7 μ M, 10 μ M and 13 μ M anthracene-9-carbonyl- N^1 -spermine in water with 200 μ M calf thymus DNA. Note broadening and magnitude decrease of 250 nm band absorbance; this molecule intercalates between DNA base pairs.

signal (this can be up to 50%) and a shift to the red (bathochromic shift) of between ~ 2 nm and 20 nm as illustrated in **Figure 7**. The DNA spectrum is also affected by any molecule such as an intercalator that causes a structural change. This makes such spectra a useful probe of DNA/drug interactions but renders absorbance useless for concentration determinations unless the perturbed extinction coefficients are known.

Titration

The label 'titration' is used to cover experiments where spectra are collected as a function of concentration, ionic strength, pH, etc. To minimize macromolecule consumption and also (perhaps surprisingly) to minimize concentration errors, the best method is often to add solution to the cuvette. A simple way to avoid dilution effects is to proceed as follows. Consider a starting sample that has concentration x M of species X . Each

time $y\text{cm}^3$ of Y is added, also add $y\text{cm}^3$ of a $2x\text{M}$ solution of X . The concentration of X remains constant at $x\text{M}$. Many variants on this theme may be derived.

If a titration series where ligand concentration is held constant while the macromolecule varies has a constant absorbance at a wavelength, λ_i , where the ligand absorbs this is called an isosbestic point. Isosbestic points only occur if two species are present in solution and those species have the same absorbance at λ_i .

Binding Constants

If the spectral shape of a ligand spectrum remains unchanged during a titration experiment, but the magnitude changes in a manner that is proportional to the concentration of bound ligand then the spectral data can be used to determine the equilibrium binding constant, K . This is because in such a case the ligands are binding in one binding mode or in constant proportions in more than one mode (meaning site, orientation, sequence, etc.). The data must be of very high quality for absorbance (or any other spectroscopic data) to be used to determine K . A simple plot of change in absorbance versus either macromolecule or ligand concentration (whichever is being varied) will probably enable the quality of the data set to be determined. It should be a smooth curve.

Consider the equilibrium

where L_f is a free ligand, L_b is a bound ligand and S_f is a free site. In the simple case where the macromolecule can be treated as a series of binding sites of n residues in size, then the total site concentration $S_{\text{tot}} = [M]/n$, where $[M]$ is the residue concentration of the macromolecule. (For proteins it is sometimes preferable to think in terms of the concentration of molecules rather than residues. In this case $S_{\text{tot}} = n'[M]$ where n' is the number of binding sites per protein.) Then

$$K = \frac{nc_b}{c_f[M]}$$

where c_b is the concentration of the bound ligand and c_f is the concentration of the free ligand.

There are a number of methods for determining K using absorbance data. The simplest is the enhancement method. This method is commonly used for fluorescence spectroscopy and may also be used to interpret absorbance data. One can write

$$\begin{aligned} c_{\text{tot}}A &= c_fA_f + c_bA_b \\ c_{\text{tot}}A &= (c_{\text{tot}} - c_b)A_f + c_bA_b \\ c_b &= \frac{c_{\text{tot}}(A - A_f)}{A_b - A_f} \end{aligned}$$

Application of this equation requires knowledge of the absorbance of free and bound ligand. Determining the latter requires measuring an absorbance spectrum under conditions where it is known that all the ligand is bound to the macromolecules. K may then be determined directly. A more accurate value of K will be achieved if the data is used to perform a Scatchard plot.

The Scatchard plot is based on rewriting the equation for the equilibrium constant as

$$\begin{aligned} \frac{r}{c_f} &= \frac{KS_f}{[M]} \\ &= \frac{K}{n} - rK \end{aligned}$$

where

$$r = \frac{c_b}{[M]}$$

So, a plot of r/c_f versus r has slope $-K$ and y -intercept K/n . The x -intercept occurs where $r=n$.

Other methods more commonly used with CD or LD data may be used with normal absorption data if the change in absorbance (the absorbance of the DNA/ligand system minus the absorbance of a free-ligand solution of the same ligand concentration) is used in the analysis.

Macromolecule Condensation

A UV spectrum may be used to follow the condensation of a macromolecule sample into particles, though, as discussed earlier, what is being probed is really scattering of the light rather than its absorbance. A monotonic increase in absorbance is observed above 300 nm as condensation takes place. In the case of DNA, the addition of a highly charged DNA binding ligand (such as spermine or $[\text{Co}(\text{NH}_3)_6]^{3+}$) will effect this change. Concomitantly with the increase in absorbance signal above 300 nm, a decrease in the 260 nm DNA absorbance is observed.

DNA Melting Curves: Absorption as a Function of Temperature

If there were no residue-residue interactions in a biomolecule then the UV spectrum would be independent of its geometry and the absorption spectrum would simply be the sum of the contributions from the residues as discussed earlier. This is particularly true for DNA, where π - π stacking interactions lower the magnitude of the absorbance at 260 nm (the hypochromic effect) and change it at most other wavelengths. The extent of this change depends on the DNA structure. In principle if the DNA is heated enough to disrupt all base structures then the spectrum would become the sum of the base spectra in appropriate proportions. A high enough temperature to achieve this cannot usually be reached in water;

Figure 8 UV melting curves for 200 μ M calf thymus DNA in 10 mM salt (denoted DNA), and also with 20 μ M spermine and 20 μ M anthracene-9-carbonyl- N^1 -spermine (denoted anthsp). Note the premelting transition with anthracene-9-carbonyl- N^1 -spermine.

however, one can use the change in the UV absorbance signal at a chosen wavelength (usually 260 nm, though at ~ 280 nm A-T base pairs show very little change in absorbance so this wavelength may be used to probe the role of G-C relative to A-T base pairs) to follow the disruption of base stacking and hence also base-pair hydrogen bonding.

The data from such an experiment is usually illustrated as a melting curve or a derivative melting curve and summarized by the so-called melting temperature, T_m (e.g. **Figure 8**). T_m is the temperature where the absorbance is the average of the duplex and single-stranded DNA absorbances where 50% of the DNA has melted. Thermodynamic data relating to the stability of the duplex may also be extracted from melting curves.

This article is reproduced from the previous edition, volume 1, pp 139–147, © 1999, Elsevier Ltd.

The techniques of flame, electrothermal and vapour generation atomic absorption, flame and inductively coupled plasma atomic emission and inductively coupled plasma mass spectrometry for the measurement of minerals and trace elements in biological specimens are described. Situations in which each of the techniques might be employed for the analysis of biomedical samples are reviewed. Interferences associated with the types of samples typically examined are mentioned with accounts of how these are removed in regular practice, either during the sample preparation or by features of the instrumentation. The advantages and disadvantages of these techniques are given with particular reference to sensitivity, single to multielement measurements and special applications such as the determination of stable isotopes. While total analyte concentrations are typically determined, examples of how speciation may be of interest are included. It is seen that for biomedical measurements, atomic spectroscopic techniques are complementary and that each may be appropriate for particular sample types or applications. Except for a few very special purposes these are the techniques of choice for measurement of minerals and trace elements in biomedical specimens.

Quantitative analytical techniques included under the general heading of atomic spectroscopy are almost always employed for the direct determination of inorganic elements. For a few biomedical applications, the specimen preparation gives indirect measurements of molecular compounds, generally by using a metal-based reagent in a separation or extraction step and measurement of the metal as a surrogate for the analyte of interest. The few examples of indirect measurements are included in the extensive reviews of atomic spectrometry published annually as the *Atomic Spectrometry Updates* (ASU).

As described in the articles on 'Theory' and 'Methods & Instrumentation' in this Encyclopaedia, analytical atomic spectroscopy concerns measurements of approximately 60 elements, generally metals, although consideration of mass spectrometry (MS) extends the range to most other elements. Biomedical applications require the measurement of almost all these elements, which are often loosely termed the minerals and trace elements. As given in **Table 1**, biological specimens contain various bulk elements which fulfill essential structural and functional roles. The trace elements, which individually account for less than 0.01% of the dry

weight of the organism, are represented by a series of elements essential to health, development and well-being (**Table 2**) and others such as lead present as contaminants from the environment. With sufficiently sensitive analytical techniques, almost all elements of the periodic table can be found and are included among the trace elements.

Figure 1 demonstrates that minerals and trace elements are relevant to a large number of disciplines which may be regarded as 'biomedical'. Some of these are

Table 1 Bulk elements found in biological specimens

Minerals	Non-minerals
Calcium	Carbon

	Phosphorus
	Sulfur

Table 2 Essential trace elements (not all are proven to have essential roles in man)

Minerals	Chromium, cobalt, copper, iron, manganese, molybdenum, nickel, selenium, silicon, vanadium, zinc
Non-minerals	Fluorine, iodine

Figure 1 The relevance of minerals and trace elements to biomedical sciences.

described in detail in related articles and are not considered further here.

From the preceding discussion it is evident that measurements of minerals and trace elements in biomedical samples are appropriate to investigations related to:

- the biological importance of essential trace and bulk elements;
- undue effects, that is the harmful consequences of a sufficiently large exposure to any element, whether essential or non-essential;
- the pharmacology of certain metals which are administered as the active principal of a pharmacological agent.

Measurements are vital to situations such as understanding mechanisms of action at cellular or molecular levels, assessing the status of, for example zinc, within an individual subject and monitoring the effects of exposure.

Many analytical techniques have been applied to the determination of minerals and trace elements but the most successful are those based on atomic spectroscopy. The techniques included in the subsequent sections afford the sensitivity required to measure concentrations below 1 ppm in specimens of just a few microlitres or milligrams with almost total specificity and relatively few interferences. As situations of deficiency and toxicity are investigated, analytes may be present at very low or very high concentrations within the same specimen type. Therefore, techniques with differing sensitivities may be used, as appropriate, for the same application. Many biomedical investigations require the measurement of just one or two metals. Consequently, multi-element techniques are not necessarily as important as in some other application areas. Nevertheless, there are situations in which this facility does become important.

Flame Atomic Absorption Spectroscopy (FAAS)

Biomedical samples and analytes

Flame atomic absorption spectroscopy (FAAS) is suitable for measurement of a limited range of elements present at concentrations greater than approximately $1 \mu\text{g ml}^{-1}$ in biological fluids, and for the analysis of solutions obtained from biological tissues at the completion of the sample preparation steps.

Typical biological fluids include blood and blood serum, blood plasma, urine and saliva. Measurement of calcium in serum was the first analysis to which the technique of AAS was applied and is an obvious example of how FAAS is useful for biomedical analysis. Other specimens, for example dialysis fluids, intestinal contents, total parenteral nutrition solutions, may be analysed on rare occasions. Elements present at a sufficiently high

concentration are lithium and gold when used to treat depression and rheumatoid arthritis respectively, and calcium, magnesium, iron, copper and zinc. Sodium and potassium can be determined by FAAS but are more usually measured by flame atomic emission spectroscopy (FAES) or with ion selective electrodes. Other elements are present in fluids at too low a concentration to be measured by conventional FAAS with pneumatic nebulization. With other fluids, for example seminal plasma, and cerebrospinal fluid, analysis may just be possible for a very few elements.

The concentrations of many metals in plant, animal or human tissues are usually much higher than in biological fluids and very often the weight of an available specimen is such that a relatively large mass of analyte is recovered into a small volume of solution, thus enhancing the concentration still further. For the analysis of tissues (these include specimens such as hair and the cellular fractions of blood) following sample dissolution steps, FAAS may be suitable for measurement of most of the biologically important elements.

Interferences and Sample Preparation

FAAS is subject to certain interferences associated with the nature of biological specimens. Mechanisms of the more important ionization, chemical and matrix interferences (Table 3) are discussed elsewhere.

Ionization Interferences

Falsely high results may be obtained because of the high concentrations of sodium and potassium, which are among the more easily ionized elements. As with matrix interferences, they may not be evident with all nebulizer–burner systems and the presence of possible interferences should be investigated with any new instrument. If ionization interference is observed the calibration solutions should be prepared with sodium and potassium at approximately the same concentration as in the test specimens. This applies to biological fluids and to solutions prepared from tissues.

Table 3 Interferences in FAAS

<i>Element</i>	<i>Interference</i>	<i>Remedy</i>
Na, K, Fe, Li, Cu, Zn Ca	Ionization	Add ionization suppressant (Cs, Na, K)
	Chemical	La, Sr, EDTA Higher temperature (greater energy)
Fe, Au, Cu, Zn	Matrix	TCA precipitation Dilution with water Dilution with detergent, alcohol Add glycerol to standards

Chemical Interferences

The only example of any consequence pertains to the measurement of calcium. The Ca^{2+} ion forms a refractory phosphate molecule, and atomization is thereby impaired. Diluents containing La^{3+} or Sr^{2+} , preferentially, bind to the phosphate and release Ca^{2+} , or EDTA to complex Ca^{2+} in solution allowing its release in the flame, effectively eliminating this interference. An alternative strategy is to use the hotter nitrous oxide–acetylene flame. A few other chemical interferences have been recorded in atypical settings and are not relevant to biomedical samples.

Matrix Interferences

Two examples occur with biomedical specimens.

- (a) Typical biological fluids contain protein and other macromolecules which increase the sample viscosity compared with simple aqueous solutions. The viscosity may reduce the aspiration rate through the narrow capillary tubing of the pneumatic nebulizer, and absorbance signals will be attenuated compared with aqueous calibration solutions, giving falsely low results. Techniques to eliminate these effects include:
 - Dilution of the sample with water (**Table 4**): A fivefold dilution is usually sufficient but some nebulizers may require a larger sample dilution to equalize the aspiration rates. Dilution may, however, reduce the analyte concentration to below the useful working range. If so, a lower dilution can be tolerated by matching the viscosity of the calibration and sample solutions by either addition of dilute glycerol to the calibrants or addition of agents such as butanol, propanol or Triton X-100 to the sample. Whatever measure is adopted it is important to determine the aspiration rates of calibration and test solutions to demonstrate that the corrective action has been effective.
 - Precipitation of the protein with concentrated acid and removal by centrifugation: trichloroacetic acid or nitric acid are used for this purpose.
 - Use of matrix-matched calibration solutions: Either protein is added to the solutions or certified reference materials are used (if available).
 - Standard additions for calibration.

Table 4 Typical dilution factors for measurements of minerals in serum or urine

Gold	1 + 1
Iron	1 + 1
Copper, zinc	1 + 1 >> 1 + 4
Lithium	1 + 9
Potassium	1 + 19
Calcium	1 + 50
Magnesium	1 + 50 >> 1 + 100
Sodium	1 + 200

- (b) Samples with a high content of dissolved solids are liable to produce falsely high results because of non-atomic absorption or light scattering. If this occurs the analyte can be removed from the matrix by extraction into an organic solvent, or a background correction technique can be employed.

Flame Composition

Elements in biomedical specimens which may be measured by FAAS are determined using the air–acetylene flame. The more refractory metals, requiring a higher temperature nitrous oxide–acetylene flame for atomization are at concentrations too low to be determined by flame atomization (except in a few tissue specimens or in indirect methods). Other flames which have historically been used for special applications now have no real place in the analysis of biomedical samples.

For most elements the proportion of acetylene to air in the flame has little influence on formation of the ground state atomic vapour, and a large variation in flow rates can be tolerated. The important exception is calcium which, as shown in **Figure 2a**, is more efficiently atomized in a reducing, fuel-rich flame. The position of the light path in the flame is also more critical for calcium than for other elements (**Figure 2b**). Modern computer-controlled instruments are pre-programmed by the manufacturers to operate under optimal conditions.

Nebulization and Sensitivity Enhancement

Pneumatic nebulizers were the original devices to introduce the sample as an aerosol into the flame gases. Despite the inefficiency of these nebulizers, coupled with depletion of the atom population in the flame, there are advantages of speed, precision and simplicity, and they have never been replaced by other devices. In practice, there can be blockages associated with particulate matter in biological materials, precipitation of protein on the inner wall of the capillary tube and the viscosity effects referred to previously. However, daily cleaning and maintenance will usually obviate these difficulties. Techniques to improve sensitivity, so as to allow the positive features of flame atomization to be retained, are widely applied to the analysis of biomedical specimens. These involve atom trapping, preventing dispersal of the atoms, pre-concentration by liquid–liquid extraction and pre-concentration using solid-phase traps.

Atom Trapping

Ground state atoms condense onto the surface of a water-cooled tube placed above the burner head and below the light path. Dilute solutions are nebulized for periods of up to several minutes to trap the analyte. Then the water

Figure 2 (a) The effect of increasing the proportion of fuel in an air-acetylene flame on the absorbance given by a solution of calcium. (b) The effect of raising the light path above the burner head on the absorbance given by a solution of calcium.

is displaced by air with a rapid rise in temperature of the trap so that all the atoms are released together into the light path to give a strong atomic absorption signal. The technique has been applied to the measurement of cadmium and lead in urine.

Preventing Dispersion of the Atoms

A hollow tube is mounted on the burner and the light path passes along the length of the tube. Samples are nebulized and atoms enter the tube where they are prevented from dispersing throughout and beyond the flame by the physical presence of the tube. Consequently, a more concentrated atom population is favoured with an improved atomization signal. Such devices were employed for the Delves' microcup technique for solid sample introduction directly into the flame – a procedure

which is still used in a few laboratories for the measurement of lead in blood. More use is made of the slotted quartz tube and a number of different designs have been used. The tube is best suited for more volatile elements (e.g. Cd, Cu, Pb and Zn) and sensitivity enhancements of 3- to 10-fold are obtained. Furthermore, with the greater sensitivity, larger specimen dilutions can be made so that matrix interferences are eliminated or specimens of small size can be analysed.

Pre-concentration methods are employed to enhance sensitivity for FAAS and for other atomic spectrometric techniques. These are described in a later section.

Electrothermal Atomization Atomic Absorption Spectroscopy

Electrothermal heating for sample vaporization has proven to be an extremely powerful tool for atomic absorption, atomic emission and for introduction of atoms into the sampling torch for inductively coupled plasma (ICP) MS. With the exception of a few designs modelled on the graphite rod, all commercial systems are developments of the Massman furnace, and are constructed from graphite. As explained elsewhere, electrothermal atomization atomic absorption spectroscopy (ETAAS) affords considerable improvements in sensitivity compared with FAAS, and the higher temperatures attained permit the measurement of elements such as Al, Cr and V which do not form an appreciable population of ground state atoms within the air-acetylene flame. Because of the small sample volumes required, less than 50 μ l, the technique is ideal for biomedical applications which are often characterized by limited material (as in paediatric investigations).

Biomedical Specimens and Analytes

A glimpse at any of the ASU reviews immediately shows that ETAAS is used for the analysis of all specimen types within the biomedical field and for the determination of virtually all applicable elements. With special furnace materials and linings, even the very refractory elements such as boron and the rare earths can be measured with useful sensitivity.

Although not extensively exploited, non-liquid samples can be accommodated. Tissue samples may be loaded into the furnace but this is a cumbersome procedure and because only a few milligrams of material can be taken it is essential that the original specimen is homogeneous – which rarely applies to biological tissues. However, it is possible to prepare suspensions of finely powdered solid samples in a thixotropic medium and the resultant slurry may then be handled as if it were a liquid and be injected into the furnace. Analyses of tissue specimens as slurries are regularly reported.

Interferences

As explained by L'Vov, who first introduced the technique of ETAAS, electrothermal atomization is ideally accomplished under stable, isothermal conditions. However, the essential design of the Massman furnace imposes dynamic conditions with complex temperature profiles both temporally and spatially within the furnace. While this allows for simplified operational designs it does however, lead to more interferences. The topic of interferences is dealt with in more detail in other articles. Of special significance to biomedical specimens, which typically contain large amounts of sodium, chloride and carbon-based biomolecules, are the following.

Drying

Protein-rich viscous specimens may dry unevenly with 'explosive sputtering' at the start of the ash phase, causing poor reproducibility.

Ashing

Volatile halides, for example AlCl_3 may form, causing pre-atomization loss of the analyte.

Atomization

Stable compounds such as carbides can be produced, giving low atomization rates (e.g. Mo); vapour phase reactions, especially molecular condensation at the cooler ends of the furnace (e.g. $\text{Pb(g)} + 2\text{NaCl(g)} \rightarrow \text{PbCl}_2\text{(g)} + 2\text{Na(g)}$), can result in non-atomic absorption of incident radiation and scattering of incident radiation by particulates (carbon, smoke, salts). The majority of developments since the introduction of ETAAS are concerned with the elimination of these interferences.

Furnace Materials and Design

Commercially available furnaces are all made from electrographite, electrographite with a pyrolytic coating or total pyrolytic graphite. Devices that delay atomization until the temperature of the gas in the furnace has reached a plateau are described elsewhere. The L'Vov platform is widely used with biomedical specimens, especially in larger furnaces, which are slow to heat to the atomization temperature. A second device, the graphite probe, produces a less sensitive analytical arrangement and is not often used. Transverse heating causes less of a temperature difference between the centre and ends of the furnace compared with longitudinal heating of the conventional Massman design and, therefore, vapour phase condensation is reduced. An authoritative review of materials suitable for use in furnace construction, and of recent developments in design, has been prepared by Frech (see Further reading).

Chemical Modifiers

Effective analysis of most biomedical materials requires addition of reagents that modify the behaviour of the specimen during the heating program so as to reduce the interferences described earlier. The chemical modifiers most commonly employed with these specimens are given in **Table 5**. Triton X-100 is used at a concentration of around 0.1% and is included in with the sample diluent. Gaseous oxygen or air are effective ashing aids but will cause rapid deterioration of the graphite furnace unless a desorption step is included before the temperature is increased for atomization. Other modifier solutions can be included with the sample diluent or separately added by the autosampler to the specimen inside the furnace. The choice of modifier often depends on the availability of a source material which is free from contamination.

Background Correction

Background correction is essential for almost all biomedical applications to correct for non-atomic absorption of the incident radiation. Non-atomic absorption is much reduced at wavelengths above 300 nm, but this is relevant to just a few elements. Each of the techniques for background correction (**Table 6**) have their advantages and disadvantages. The three systems used in commercial instruments are effective although the

Table 5 Chemical modifiers used in the analysis of biomedical specimens by ETAAS

Modifier	Purpose
Triton X-100	To ensure smooth, even drying of protein-rich specimens and avoid the formation of a dried crust around a liquid core
Gaseous oxygen	To promote destruction of the organic matrix and reduce formation of smoke and other particulates which give non-atomic absorption
Ni, Cu, Pd	To stabilize volatile elements, e.g. Se, and As, during the dry and ash phases
Potassium dichromate	Stabilizes Hg up to a temperature of 200 °C
HNO_3 or NH_4NO_3	To stabilize analyte atoms by removal of halides as HCl or NH_4Cl during the ash phase
$\text{Mg(NO}_3)_2$	Becomes reduced to MgO which traps the metals to reduce volatilization losses and also to delay atomization and separate the analyte signal from the background absorption
$\text{NH}_3\text{H}_2\text{PO}_4$ or $(\text{NH}_3)_2\text{HPO}_4$	Usually used together with magnesium nitrate; reduces volatilization losses and also delays atomization to separate the analyte signal from the background absorption

Table 6 Background correction (BC) techniques

Measure absorbance at a nearby non-absorbing line
Deuterium BC
Smith-Hieftje BC
Zeeman-effect BC; (i) applied to the light source
(ii) applied to the furnace

Smith-Hieftje variation is included by very few manufacturers. The Zeeman-effect technique is ideal for dealing with structured background which is of particular significance in the measurement of cadmium in urine and elements such as arsenic and selenium in iron-rich samples, that is blood. Without Zeeman-effect background correction, these applications are difficult to carry out successfully by ETAAS.

Novel Atomizers

Several research groups have designed atomizers with the purpose of separating the analyte from interfering species to permit simple atomic absorption. While some appear to be effective, none are commercially available. It was shown some years ago that a 150 W tungsten filament from a light bulb could be used as an electrothermal atomizer. More recently, this concept has been used to develop very small portable instruments for onsite measurement of lead in blood. Excellent results have been reported but a commercial model is still awaited.

Other Techniques for Atomic Absorption Spectroscopy

Biomedical Samples and Analytes

The technical and instrumental features of cold vapour and hydride generation are described elsewhere. Mercury is used extensively in industry and there may be situations of environmental use, but the typical sources of exposure are from the diet, especially fish, and from dental amalgam. Depending on the nature of the exposure, for example inorganic salts, organomercury compounds and the metal or its vapour, it may be necessary to analyse specimens of urine, blood or tissues and foods. Many of the elements which form volatile hydrides have important biomedical properties. Selenium is an essential micro-nutrient, arsenic is especially recognized as toxic while bismuth and antimony have valuable pharmacological properties. As with mercury, all types of biological specimens may require to be analysed.

Mercury: Cold Vapour Atomic Absorption Spectrometry

The concentration of mercury in urine is an excellent indicator of recent exposure to mercury vapour or inorganic compounds, and the measurement is very simple

following digestion with $\text{KMnO}_4\text{--H}_2\text{SO}_4$ to ensure that all carbon-mercury bonds are broken. With other samples, a more aggressive approach is required to not only release the mercury but also destroy the organic matrix which inhibits vaporization of elemental mercury. These more powerful reducing conditions and heating are necessary for analysis of blood and tissues. To prevent loss of volatile mercury either a closed digestion system or heating with a reflux condenser must be used.

Because the clinical and toxicological effects of alkylmercurials are so different from those of inorganic species, it is useful to measure organomercury compounds separately. The essential reaction to the cold vapour technique is the reduction of Hg^{2+} to Hg^0 . Thus, total mercury concentration in a specimen will be determined after the disruption of carbon-mercury bonds, as described earlier, while if this step is omitted only the inorganic mercury is measured.

Hydride-forming Elements

Considerable interest in methods to measure arsenic and other hydride-forming elements has been evident in recent years. The basic procedure involves careful digestion of the specimens to convert all the different species to a single valency form, reduction with BH_4^- and vaporization to the hydride, followed by atomization in a quartz tube heated in an air-acetylene flame or with electrical thermal wire. However, measurement of total arsenic is not always entirely helpful. Fish contain large amounts of organoarsenic species which are absorbed and excreted without further metabolism and with no adverse health effects. These species will be included in a total arsenic determination and can mask attempts to measure toxic As^{3+} and metabolites. Thus, methods to measure the individual species, or related groups of compounds in urine or other samples, have been described to provide more meaningful results. These methods include separation by chromatography or solvent extraction and pre-treatment steps which transform only the species of interest into the reducible form.

Accessories from instrument manufacturers for hydride generation allow for either a 'total consumption' measurement when all the sample is reacted at once with the BH_4^- and the gaseous hydride taken to the heated cell as a single pulse or by flow injection to give a continuous, steady-state signal. The former gives a lower detection limit but the latter is easier to automate. The chemical hydride reaction is impaired by other hydride-forming elements and by transition metals so that careful calibration is essential. It has been shown that the hydride may be taken to a graphite furnace where the gas is trapped onto the surface. Rapid electrothermal heating then gives a very sensitive signal. Trapping is more efficient when the graphite is coated with a metal salt, for

example Ag, Pd, and Ir. Electrolysis releases nascent hydrogen and this reaction has been employed as an alternative to chemical hydride generation. With this arrangement the interferences are much less.

With careful sample preparation hydride generation is an extremely valuable analytical technique appropriate to ICP-AES and ICP-MS as well as atomic absorption spectrometry. Within the context of biomedical analysis, measurements of arsenic and selenium are currently the more important.

Atomic Emission Spectroscopy

Flame Atomic Emission Spectroscopy

Of the different techniques for atomic emission spectroscopy (AES) only those which use a flame or an ICP are of any interest for analysis of biomedical specimens. FAES, also called flame photometry, has been an essential technique within clinical laboratories for measuring the major cations, sodium and potassium. This technique, usually with an air-propane flame, was also used to determine lithium in specimens from patients who were given this element to treat depression, and was employed by virtually all clinical laboratories throughout the world until the recent development of reliable, rapid-response ion-selective electrodes. Biological fluids need only to be diluted with water, and in modern equipment the diluter is an integral part of the instrument so that a specimen of plasma or urine can be introduced without any preliminary treatment.

Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES)

At the temperature of the flame there is no useful emission of other biologically important elements. However, with the greater energy of the ICP, much lower detection limits, typically around $1 \mu\text{g ml}^{-1}$, are obtained and many elements may be determined in solutions prepared from biological tissues. Recent developments with the optical systems and array detectors offer improvements in sensitivity and data collection. In consequence, elements such as copper, zinc and aluminium may be measured in blood plasma, while the expanded information caught by detectors is making it possible for powerful chemometric manipulation of individual signals to be undertaken.

The most valuable features of ICP-AES is the multi-element capability. In most clinical situations this is not an important requirement but for some research work and in other biomedical applications the comprehensive information derived can be of considerable interest. There are few interferences associated with ICP-AES but, as with FAAS, matrix interferences associated with

uptake of sample via the nebulizer may be encountered with some systems.

Inductively Coupled Plasma Mass Spectrometry (ICP-MS)

Other instrumental approaches to inorganic MS are available which, together with X-ray fluorescence spectroscopy, are mainly applied to the analysis of very thin solid specimens such as tissue sections. For more general application, the ICP as the ion source has provided enormous improvements to inorganic MS. These improvements include convenience to operate, low detection limits ($\mu\text{g l}^{-1}$ or below), multielement analyses and the ability to measure isotopes, thus allowing stable isotopes to be used as tracers for metabolic and other studies. However, there are important disadvantages associated with ICP-MS. Sampling times of several minutes at a nebulization rate of approximately 3 ml min^{-1} are required to ensure a sufficient number of counts at each mass number and, therefore, the volume of undiluted specimen necessary to give a result can be large. As a consequence of the long sampling times and the frequent measurement of blanks, calibration specimens and quality control samples, the total number of real specimens analysed in a working day is not high. With a slow rate of analysis, the requirement for experienced staff and the very high capital and servicing expenditure, the measurement costs are extremely high.

Interferences and Sample Preparation

Matrix interferences affecting the nebulizer are similar to those of FAAS and ICP-AES, and sample preparation generally involves dilution or acid digestion of liquid specimens and digestion or solubilization of tissues. In addition, some suppression of analyte signals may be caused by sodium and other dissolved inorganic components. To overcome this the salts may be removed by chelating resins or by using reference materials with a composition similar to the test specimens as calibrants. Of greater importance, ICP-MS is subject to a number of spectral interferences due to the formation of polyatomic species with the same mass number as the element being measured. For example, in the determination of zinc there are interferences due to sulfur ($^{32}\text{S}^{16}\text{O}_2$, $^{33}\text{S}^{16}\text{O}_2\text{H}$ and $^{32}\text{S}^{16}\text{O}^{18}\text{O}$) and chlorine ($^{35}\text{Cl}^{16}\text{O}_2$) on ^{64}Zn , ^{66}Zn and ^{67}Zn . Various techniques to reduce spectral interferences include the use of ion-exchange, either off-line or on-line (usually an HPLC column) or liquid-liquid extraction, to separate the analyte from the interferants or to count an isotope which is relatively free from interferences. The more recent generation of high-resolution mass spectrometers is reported to give good discrimination of analyte isotopes from other species but at a cost of higher

detection limits. To improve the signal associated with isotopes of low abundance, techniques for sample introduction that avoid the use of a nebulizer have been developed. These include mercury vapour and hydride generation, electrothermal vaporization and laser ablation techniques.

Biomedical Applications

The technique of ICP-MS is rarely appropriate for measurement of a single element. Exceptions are where sensitivity is unmatched by other techniques and for isotope work. The very low detection limits for rare earth elements and the actinides have permitted a number of studies relating to the biochemistry and unusual sources of exposure to these elements. Similarly, low levels of occupational and environmental exposure to platinum and other noble metals are now being investigated. Isotope work includes fundamental biochemical studies using isotopes of elements such as H, C, N and O; absorption and distribution of essential trace minerals, e.g. Fe, Zn, and Se in situations such as childhood, pregnancy and dietary deficiencies; and the identification of sources of exposure to lead and other non-essential elements by comparisons of isotopic compositions, i.e. a 'fingerprinting' approach. More complex investigations require a combination of these features: e.g. determination of intestinal absorption rates of different dietary selenium species involves feeding subjects with foods previously enriched with stable isotopes, and separation of the selenium species in specimens such as blood by HPLC coupled directly to the ICP-MS, which affords both very sensitive analysis and differentiation of the selenium isotopes. Indeed, speciation work such as this represents a major area of biomedical interest to which the technique of ICP-MS is applied. A further activity involves the characterization and certification of biomedical reference materials where the high degree of accuracy required is achieved by inclusion of isotope dilution analysis into the multielement measurement.

Sample Preparation

The objectives for preparation of biomedical specimens are to (1) remove interfering components from the matrix and (2) adjust the concentration of analyte to facilitate the actual measurement. These objectives may be realized by a number of approaches (Table 7) which in general are appropriate to all the techniques described in this article.

Methods for destruction of the organic matrix by simple heating or by acid digestion have been used extensively and are thoroughly validated. Microwave heating is now well established for this purpose with specifically constructed apparatus to avoid dangers of

Table 7 Approaches to sample preparation

<i>Procedure</i>	<i>Remarks</i>
Dilution, protein precipitation	Using simple off-line arrangements or flow-injection manifold
Dry ashing	Using a muffle furnace or a low-temperature asher
Acid digestion	(i) In open vessels with convection or microwave heating (ii) In sealed vessels to increase the reaction pressure
Base dissolution	Using quaternary ammonium hydroxides
Chelation and solvent extraction	For analyte enhancement and removal of interferences
Trapping onto solid-phase media	For analyte enhancement and removal of interferences

excessive pressure within reaction vessels. Although the number of specimens which can be processed is not large, microwave heating affords rapid digestion and low reagent blanks. More recent developments include continuous flow systems for automated digestion linked directly to the instrument for measurement of the analyte(s).

Pre-concentration by liquid-liquid partitioning is a widely used procedure. Analyte atoms in a large volume of aqueous specimen are complexed with an appropriate agent and then extracted into a smaller volume of organic solvent. This leads to enhancement of concentration and also removes the analyte from potential/real interferences in the original matrix. It is used to measure lead in blood and metals in urine and for other applications. Pre-concentration by trapping onto solid-phase media represents the area where much of the recent interest in FAAS has been focussed but is relevant to all sample-preparation work. The original work involved adsorption onto material such as charcoal or alumina but newer phases include ion-exchange resins and novel support systems to which functional groups are added to confer increased selectivity and capacity. While trapping of an analyte from a dilute sample and elution into a small volume of release solution may be accomplished off-line, developments in flow-injection analysis provide for the assembly of simple on-line manifolds so that complete measurements may be carried through automatically. Developments in these applications involving a wide range of biomedical sample types and elements are regularly described in the ASU reviews. Biological reference materials with and without certified values are readily available and several interlaboratory comparison programmes are established for analysts to determine the accuracy of their methods.

Introduction

Metallomics encompasses and juxtaposes the traditional fields of bioinorganic chemistry and atomic spectroscopy to better define and characterize the abundance, role, and function of metal moieties in biological systems. The metallome, in extension to the proteome, metabolome, transcriptome, and so forth, comprises the complete complement of all metals in a biological fluid, tissue, or structure, whether ionically or covalently bound, complexed, or existing simply as free metal ions. At least 20 metals are important biologically, and another 8–10 may have varied, organism-dependent roles. The analytical challenges associated with characterizing the metallome are significant, as metallomics implies the global characterization of metals, the concentration range of which may span over 14 orders of magnitude, from percent levels to subparts per trillion (by volume). The extension to metalloid elements also brings into play the biologically critical elements S and P.

In addition to the characterization of natural or inherent metals in such systems, the use of metals as tags or extrinsic molecular biomarkers has become increasingly useful in the past several years. The rationale for this development has been to improve the quantitative capabilities for specific proteins or biomolecules and thus to provide more detailed information relating to their flux and dynamics. The improved analytical performance derives from the highly specific, sensitive, and quantitative attributes that modern atomic spectroscopy is recognized for. Chief among the atomic spectrometry techniques in use for metallomics applications is inductively coupled plasma mass spectrometry (ICPMS). This article provides a brief overview of current trends and activities in the new field of metallomics, as enabled by ICPMS and closely related techniques.

Intrinsic Bioelement Determination (P, S, Se, I, and Other Metals)

Metals occur naturally with and in coordination with various biomolecules, most notably as metalloproteins. Metals themselves serve important roles as enzymatic catalysts, as cofactors, and as regulatory and other signaling agents. Biologically important metals associated with proteins primarily include Cu, Zn, Fe, Ni, Mn, and Mo. These and many other elements are easily and simultaneously determined using ICPMS. Although many metalloproteins are known and it is hypothesized that as many as 30% of all proteins exist as metalloproteins, the exact nature of the metal association, coassociation with other metals, and the temporal and dynamic nature of the metalloproteins are many times unknown and remain largely uncharacterized. In certain cases, some proteins can have several metals associated within their structures, and the existence of all the metal partners has gone unrealized until serendipitous discovery of this fact. The case for global metal characterization is thus made.

The metalloid elements P, S, Se, and I also occur naturally in biological systems. Phosphorus is an integral component of DNA and RNA genetic structures and a primary constituent of phospholipids, and of course, protein phosphorylation is the predominant type of post-translational modification of proteins. Sulfur occurs in the amino acids cysteine and methionine, and hence is widely found in proteins and constituent peptides. A number of important studies using ICPMS for protein quantification using either P or S as analytical probes have been conducted. Despite the fact that for conventional ICPMS these elements are among the least sensitive and most interference-prone, novel and uniquely specific detection using modern collision/reaction cell technologies for interference reduction have enabled impressive quantitative results. Selenium is also incorporated as a sulfur analog into the amino acids selenocysteine and selenomethionine, as well as a number of selenoproteins. Selenium is also a difficult element to determine by ICPMS, owing to its many isotopes, its relatively high ionization potential, and its spectral location (m/z , 78–82) where many argon dimer (Ar_2^+) species (emanating from the plasma support gas) also occur. Iodine, reasonably sensitive by ICPMS, finds use as a metabolic messenger in the human thyroid hormone thyroxine and has been the target of selected metallomic studies.

Extrinsic Metal Tag Determination

Biomolecules can be tagged and quantified very effectively by incorporating metals as a complex or chelate, a labeled antibody, or as a bioassociated nanoparticle. Each of these methods has found use in improving the selectivity or sensitivity of analysis for particular species. The use of bifunctional chelating agents that enable incorporation of a suitable metal tag and allow for subsequent separation and purification of the tagged species via affinity enrichment methods has become quite common and popular. Lanthanides are excellent metal tags owing to their high ICPMS sensitivity, the number of them available to choose from (allowing multiplexed assays using different lanthanide elements and their isotopes), and their low natural background in biological systems. Additionally, highly efficient and effective lanthanide complexing agents are available (developed originally for immunological and radio-immunological purposes), the most prevalent and useful of which are DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) and DTPA (diethylene triamine pentaacetic acid). The DOTA reagent has been modified to target and tag cysteine residues, using antibodies to selectively retain and chromatographically separate labeled and digested peptides, enabling multiplexed quantitation. This approach is termed the element-coded affinity tag (ECAT) approach. A similar approach (metal element chelate tag, MECT) using DTPA is also in use (see 'Further Reading'). This reagent labels all primary amines and is thus more universal for protein quantification. DTPA, along with specially designed multifunctionalized (multimetal, multi-tagable) polymeric antibody reagent tags, is also used by the Canadian DVS Sciences, Inc. group to enable highly multiplexed detection, using a purpose-built ICP-TOF-MS instrument. This capability provides single-cell/ bead cytometric analysis for proteins or DNA using lanthanide elemental/isotopic tags. The primary analytical advantages of improved selectivity, sensitivity, and linear dynamic range afforded by atomic mass spectrometric methods are all realized in these approaches, and it is foreseen that this

approach will become more and more relevant in biotechnical assays.

Diffraction Theory and Structure Synthesis

The techniques required for the determination of three-dimensional (3D) macromolecular structures are similar to those used for small organic and inorganic molecules. In practice, the problems encountered are sufficiently different, so they require unique approaches for sample preparation through to structure refinement. The hardware and software needed for the work are specific to this field of research. Diffraction theory states that for the determination of structures at atomic resolution (interatomic spacing $\sim 1 \text{ \AA}$), the use of radiation with wavelength of the order $\sim 1 \text{ \AA}$ is required. Imaging theory, such as that used in optical microscopy, would be appropriate if it was not for the fact that the refractive index of most materials, with respect to X-rays, is close to unity, making it impossible to manufacture lenses for imaging the sample. Measured data are therefore diffraction patterns, and the ideas most useful for data handling have more in common with spectroscopic methods. This said, diffraction arises from elastic rather than from inelastic scattering and is not an absorption phenomenon with the exception of anomalous dispersion, which uses absorption and dispersive effects close to an atomic absorption edge to obtain structural information. The crystalline nature of the sample results in discrete diffraction patterns or diffraction spots rather than a continuous diffraction. The positions of diffraction spots, in reciprocal space, are defined by integer numbers or Miller indices (h, k, l) and X-ray scattering by the measured intensity $I(h, k, l)$. Intensities are proportional to the number of scattered X-ray photons and are related to the structure amplitude by $I(h, k, l) = |F(h, k, l)|^2$. The structure factor is the amplitude with associated phase such that $F(h, k, l) = |F(h, k, l)| e^{i\phi(h, k, l)}$. The electron density $\rho(x, y, z)$ at a point (x, y, z) in the crystallographic unit cell of volume V can be calculated by Fourier transform, which relates the spectral diffraction components in scattering or reciprocal space to the electron density in real space. In the following discussions, indices will be abbreviated to the vector $\underline{h}$ and coordinates x, y, z to the vector $\underline{r}$.

$$\rho(\underline{r}) = \frac{1}{V} \sum F(\underline{h}) e^{-2\pi i(\underline{h} \cdot \underline{r})} \quad [1]$$

The summation is over all Miller indices of the data set. It is sometimes useful to perform the reverse operation to

obtain the structure amplitude and phases by inverse Fourier transform of the electron density.

$$F(\underline{h}) = \int \rho(\underline{r}) e^{2\pi i(\underline{h} \cdot \underline{r})} dV \quad [2]$$

The above integral is over a unit cell. Because $F(\underline{h})$ contains both amplitude and phase, it contains equivalent information on the structure as the electron density map.

Crystal Symmetry

The unit cell is the smallest crystal volume that contains a collection of asymmetric units (molecules) that are related by crystallographic symmetry operations. The crystal is formed by a translational repeat of the unit cell in three dimensions. Crystal types fall into seven crystal systems with increasing complexity of internal symmetry. Understanding symmetry rules and correctly assigning them to the crystal being investigated is essential to structure determination. The simplest crystal system is triclinic, which allows any cell dimensions and angles for the unit cell and, at most, only an inversion center of symmetry. The highest symmetry crystal system is the cubic cell where all the cell dimensions are equal ($a = b = c$), and angles ($\alpha = \beta = \gamma$) must be 90° . The internal symmetry elements can be combinations of rotational and screw axes, mirror planes and glide planes, whereas the Bravais lattice types can be P, I, or F. P is a primitive lattice (points at cell corners), I has an additional lattice point at the center of the cell, and F also has lattice point at the center of each of the six cell faces. For the monoclinic and orthorhombic space groups, there is also the lattice type C with an extra lattice point centered on one of the faces. For trigonal space groups that are characterized by a highest symmetry threefold rotation point group element, a rhombohedral lattice R as well as P is also possible. The internal symmetry is first defined by the point group formed from rotation axes and mirror planes. Translational symmetry elements, such as screw axes and glide planes, complete the description. There are 230 possible space groups, defined mathematically by a transformation of general coordinates by space group symmetry elements to generate all the copies within the unit cell. The task is to determine atomic coordinates for the crystal at hand. Macromolecules are chiral and only L-amino acid enantiomers

Table 1 The distribution of Bravais lattices, point groups, and space groups within the seven crystal systems^a

Crystal system	Number of point groups	Bravais lattices	Number of space groups
Triclinic	2 (1)	P	2 (1)
Monoclinic	3 (1)	P, C	13 (3)
Orthorhombic	3 (1)	P, C, I, F	59 (9)
Tetragonal	7 (2)	P, I	68 (16)
Trigonal	5 (2)	P, R	25 (11)
Hexagonal	7 (2)	P	27 (12)
Cubic	5 (2)	P, I, F	36 (13)
Total	32 (11)		230 (65)

^aThe numbers in brackets are those allowed for biological macromolecules.

are normally in proteins; hence, coordinate inversion and mirror/glide planes are not allowed as these operations transform L-amino acids into D-amino acids. For this reason, only 65 space groups are possible for macromolecular crystals (Table 1). A full description of space groups and their symmetry elements can be found in the *International Tables for Crystallography, Volume A*.

Space Group Symmetry

Four symbols are used to describe space group symmetry. The Bravais lattice type P, C, I, R, or F, followed by three symbols that describe symmetry elements along each crystal axis. For biologic molecules, these will be rotation or screw axes symbols. For example P12₁1 describes a primitive cell (P) with no symmetry element along the *x* and *z* axes and a twofold screw axis along the *y*-axis, and comprises a 180° rotation around the *y*-axis followed by a half translation along *y*. Such a symmetry transformation will move a coordinate *x*₁*y*₁*z* to a point $-x, 1/2 + y, -z$ and define two copies of the asymmetric unit in the unit cell. The consequence of this is that eqns [1] and [2] must be expanded to take these symmetry elements into account, and this has a profound effect on the observed symmetry of the diffraction patterns and whether or not diffraction spots are allowed for any specific set of indices *h*.

Assigning the Space Group

The first step in assigning the space group is to determine the crystal system, which is done by finding the cell dimensions *a*, *b*, *c*, α , β , and γ , which predict the diffraction pattern. This will establish whether any equalities exist, such as $a = b \neq c$, $\alpha = \beta = \gamma = 90^\circ$ (tetragonal). Data are measured in a trial space group that provides a measured set of indices with associated intensities. For a full assignment of space group, it is also necessary to determine the point group symmetry of the diffraction pattern and that the intensities of symmetry-related reflections should

agree. A rule of thumb is that for a correct assignment the agreement between intensities should be ~10%. The Bravais lattice type and the presence of screw axes can be established through systematically absent reflections that are missing because of translational symmetry elements. The process of space group assignment has been made easier by software tools (Pointless, Xtriange, and Xprep) that analyze statistically the presence of point group symmetry and systematic absences. However, for enantiomorphic space groups such as 4₁ and 4₃, the systematic absences are ambiguous and are consistent with either assignment. Inspection of electron density maps, calculated in the alternative space groups, can reveal the correct space group by looking for expected chemical structures such as α -helices of the correct hand and L-amino acids.

Sample Preparation and Crystallogenesis

The preparation of crystals requires highly purified protein samples usually made by recombinant methods. Genomic sequencing projects provide a vast amount of DNA sequence information encoding protein sequences. The coding DNA can be extracted from genomic DNA and inserted into a plasmid, which is reproduced by a bacterium such as *E. coli* and protein expression chemically initiated in the bacterium. Purification has been made easier by engineering terminal affinity tags such as 6xHis, which preferentially bind to an Ni chromatography column. Growing crystals is still a challenge especially in the case of membrane proteins. The process is a matter of trial and error, but in essence, concentrated protein (~10 mg mL⁻¹) is mixed with a chemical precipitant and equilibrated until a supersaturated state is approached, at which point crystals may form. Factors such as pH, additive chemicals, and types of precipitant can result in a vast search space to explore. The process has been made easier, in recent years, by the availability of commercial screens made in 96-well format and crystallization and visualization robots that eliminate some of the human error and require less protein for the initial trials. Drop sizes as small as 100 nl can be achieved, which allows several 96-well trays to be prepared from as little as 100 μ l of protein.

Data Collection

The elements of data collection are an X-ray source, a detector, a method for controlling the crystal sample, and software for processing the data. The technologies have changed greatly over the years so that methods for collecting and processing data are now rapid and, in some cases, have been automated for structural genomic

projects that require high-throughput approaches for handling ever-increasing numbers of crystal samples.

X-ray Sources

The first X-ray sources were evacuated sealed tubes in which electrons emitting from a 40 kV tungsten filament were focused onto a metal target. The absorbing target material re-emits energy as characteristic X-ray emission lines lying on top of bremsstrahlung radiation. Although convenient, the power dissipation of these devices and hence their X-ray output are low. Modern X-ray generators use rotating anode technology to dissipate heat energy more efficiently to achieve higher X-ray output. Improvements have also been achieved by increasing electron focusing coupled with confocal optics that can collect and focus the X-ray beam into an intense micro-focus beam.

For even more intense beams that have better optical properties, synchrotron storage rings are needed. These X-ray sources utilize charged particles, accelerated to relativistic speeds, as the source of spontaneous X-radiation. Increases in intensity arise from relativistic effects that cause emitted radiation to be observed within a narrow cone of radiation. The opening half-angle $1/\gamma$ of the cone is given by the inverse of the relativistic Lorentz factor γ . To achieve less than milliradian opening angles requires high-energy storage rings operating at several GeV. Typically, synchrotron radiation source energies, used by crystallographers, are in the range 2.0–8.0 GeV, peaking at wavelengths in the range 4.0–0.5 Å. Additional increases in intensity can be attained with insertion (magnet) devices placed in the straight sections of the storage ring. Multipole wigglers multiply the radiation sources by the number of magnetic poles of the wiggler, whereas undulators employ interference effects, by smaller magnetic deviations, producing output X-radiation over a narrow spectral range at interference harmonics. Both multipole wigglers and undulators are sufficiently broad in their bandwidths for anomalous dispersion measurements (see MAD phasing); however, undulators have reduced emission angles and provide higher beam brilliances several orders of magnitude larger than a bending magnet. A multipole wiggler is of advantage if the entire spectrum from 0.5 to 2.0 Å is required for Laue data measurements in fast time-resolved diffraction experiments. At its simplest, the layout at a synchrotron beamline consists of optics to condition the beam, a motorized rotation axis to change the orientation of the sample, and a detector to record images (**Figure 1**).

Detectors

The usual method for collecting macromolecular single crystal data is in rotation camera geometry. The crystal

Figure 1 A simplified schematic layout at a synchrotron facility of a macromolecular crystallography experiment. The X-ray emitting source (S) is conditioned by a toroidal mirror (Mi) that focuses radiation in 2D at the sample. At some facilities, this is achieved by two mutually perpendicular mirrors. Collimator (C) slits present a beam of the required size at the sample (X), which is cryo-cooled (Cr) by a nitrogen gas stream at 100 K. The crystal is rotated (R) around an axis at right angles to the beam over a small rotation interval. A diffraction image, of the scattered radiation, is collected on a 2D electronic detector.

rotation axis is at right angles to the X-ray beam and data are collected on an area detector normal to the X-ray beam. Macromolecular diffraction patterns are dense (~3000 spots per image), and so area detectors are the most efficient method for collecting data. Electronic area detectors are available, which are made from doped phosphor. For example, the MAR345 image plate has a long-lived luminescent phosphor of pixel size 100–150 μm , an image diameter of 345 mm, and an image scanning time of 80 s. The RAXIS IV image plate effective readout time is faster because of a dual-plate system. Faster detectors, with readout time as low as 1 s, are now available in tiled CCD detectors coated with a phosphor emitting visible photons collected and transported through tapered fiber optics to a cooled CCD chip. The tiled CCD detectors are made in arrays as large as 4×4 (325 mm). Although CCD detectors are fast, they have problems arising from distortions in the tiled chips and fiber optics geometry that must be corrected for. Novel detectors that have fewer distortion problems and are faster are the flatbed MARresearch detector coated with an Se layer that directly converts X-ray photons into charges that are collected by a TFT pixel electrode. Another is the PILATUS pixel detector (424×435 mm, pixel size 139 μm) with a readout time of a few milliseconds. The readout speed permits a different data collection philosophy of continuous data collection and full 3D profile fitting of diffraction spots.

Cryo-Freezing

Crystals are mounted so that they may be held in the X-ray beam and rotated. A modern approach is to scoop the crystal up in a tiny loop, made of nylon or plastic attached to a solid rod, which is then flash-frozen in liquid nitrogen. During data collection, crystals are bathed in a continuous flow of nitrogen gas normally at the temperature 100 K. Cryo-freezing reduces radiation

damage from the X-rays, as well as reducing data noise due to atomic thermal motion. Untreated crystals often crack if flash-frozen; therefore, they are generally pre-soaked in a cryoprotectant solution before freezing. Soaking crystals is necessary for making heavy atom derivatives in solving the phase problem or for inserting molecular substrates in the case of an enzyme. All these may require different cryoprotectants and can be time consuming to find.

Data Processing Software

Diffraction data are collected as a large number of contiguous rotation images ($\Delta\Phi = 0.1\text{--}2.0^\circ$). Data reduction consists of three main steps. The first (autoindexing) is to determine the Bravais lattice and unit cell constants from the recorded diffraction pattern, allowing Miller indices to be associated with each diffraction spot. In the second stage (integration), the intensities of the reflections are measured by predicting the locations of the reflections and determining an average profile, and then scaling this to the observed spots. Finally, all measurements are scaled and merged, which will typically include corrections for:

- variation in the beam intensity/illuminated volume
- crystal decay
- absorption of the diffracted photons in the sample and air
- geometric factors such as Lorentz and beam polarization factors

There is a wide range of data reduction packages available to the crystallographer. The most common are HKL (Otwinowski & Minor), Mosflm (Leslie) and Scala (Evans), XDS/XSCALE (Kabsch), and d*TREK (Pflugrath). In this article, the use of Mosflm/Scala and XDS/XSCALE is covered, which are well suited to wide and fine phi-sliced data, respectively, and are free to the academic user.

Mosflm and Scala

The autoindexing and integration program Mosflm is best accessed through the GUI iMosflm. This allows a sweep of diffraction images to be loaded and will guide the user through the necessary steps (**Figure 2**). The first task of autoindexing can be performed automatically using images selected by the GUI and will, in most cases, give an adequate result. The most likely solution, that is, the highest symmetry solution with a good match between observed and predicted reflections, will be selected automatically. The cell constants and diffraction parameters should be refined before integration, after which the final processing may take place. Once the data are integrated, the rest of the data reduction may be performed through CCP4i. The 'scale and merge intensities'

task will allow data from multiple runs of Mosflm to be combined, which is necessary for multipass and multi-wavelength data sets.

XDS/XSCALE

Unlike Mosflm and Scala, XDS and XSCALE do not provide graphical user interfaces. They are instead run via plain text input files that describe the crystallographic problem and the experimental geometry. To use these programs, more understanding of data processing is required. The XDS program (<http://www.mpimf-heidelberg.mpg.de/~kabsch/xds/>) may be considered as a sequence of tools, with autoindexing performed by determining the detector corrections and background (XYCORR and INIT) and then finding the spots and indexing (COLSPOT and IDXREF). Unlike other data reduction packages, XDS will not recommend the best solution, instead it will perform all processing in the lowest symmetry space group P1. After autoindexing, the integration (DEFPIX and INTEGRATE) and postrefinement (CORRECT) are fairly straightforward. As the processing is performed in P1, it will be necessary to impose the correct point group and lattice constraints at the final step (CORRECT). Once the data from all sweeps are integrated, they may be scaled and merged with XSCALE.

Phase Problem

A problem arises in reconstructing the electron density map of the molecule using eqn [1]: the absence of experimental phases. This is the so-called phase problem. Techniques exist that estimate phase distributions by indirect means that exploit special relationships between structure amplitudes, by utilizing a known homologous structure, or by determining heavy atom substructure as a source of starting phase information. These methods constitute the most important group of macromolecular structure determination procedures. The software to do this, although similar to other diffraction techniques, have many elements that are specific to macromolecular structure determination and are in general different in their theoretical approaches as well as the instrumentation and software for achieving the tasks.

The Patterson Methods

Most methods for estimating phases use a special kind of Fourier transform called the Patterson function $P(\underline{q})$, which uses only the coefficients $|F(\underline{h})|^2$. The virtue of this is that phases are not required and only the measured quantities $I(\underline{h})$ are used. The function is an autocorrelation of the electron density distribution (ρ). The vector

Figure 2 A screen image is shown of the software package iMosflm. It processes diffraction images and provides indices and measured intensities. An image is overlaid in the top right showing calculated reflection position on top of the diffraction pattern. The GUI panes provide statistics on the progress of data processing such as fluctuation in predicted positions and angles as well as the signal/noise values as a function of resolution.

space $\underline{q} = (u, v, w)$ is related to real space coordinates $\underline{r}$ by the convolution of the electron density such that:

$$P(\underline{q}) = \int \rho(\underline{r}) \rho(\underline{q} + \underline{r}) dV \quad [3]$$

$$= \sum |F(\underline{h})|^2 e^{-2\pi i(\underline{h} \cdot \underline{q})} \quad [4]$$

A real space distribution of N atoms will create $N(N-1)$ nonorigin peaks in vector space $\underline{q}$ with the coordinates $\underline{q} = \underline{r}_1 - \underline{r}_2$ and peak heights $\rho(\underline{r}_1)\rho(\underline{r}_2)$. The vector $\underline{q}$ connects atoms, and for N atoms there are N^2 ways to do this. For a macromolecule that contains several thousand atoms, a vector space map corresponds to several million peaks, most of which are overlapping and therefore not interpretable. However, as a description of the macromolecule, it is rich in information and can be used to establish the orientation and translation of a molecule in the unit cell. For substructures of relatively

small numbers of heavy atoms, their coordinates can be obtained by deconvoluting the vectors into real space.

MIR Phasing

The original method of experimental phasing, named multiple isomorphous replacement (MIR), relies on the substitution of a few heavy metal sites, such as Hg, Au, and Pt, into the crystal unit cell to make a heavy atom derivative of the macromolecular structure. Differences in structure factor amplitudes, between native (unmodified) and derivative data sets, provide information on the heavy atom positions that can be located using Patterson or direct methods. The details for this will be discussed later in text. Once the positions have been determined, the amplitude and phases, corresponding to the heavy atom sites, can be calculated and used with the observed amplitudes of the native structure (F_p) and derivative (F_{ph}) to estimate phases of the entire structure. For only one derivative, there are two solutions to the

equations, resulting in a phase ambiguity. This ambiguity can be resolved by adding more derivative data sets, and it is common to need as many as four derivatives to achieve this. Another way to resolve the phase ambiguity is to include anomalous dispersion data for each derivative (MIRAS), thus reducing the total number of required derivatives. In favorable circumstances, a single derivative with associated anomalous difference suffices (SIRAS). Although the overall isomorphous difference can be large (30%), the difference often arises from other effects such as distortions in the macromolecular structure and changes in the unit cell parameters. These sources of amplitude differences cannot be adequately modeled, resulting in large phase errors. If differences in amplitudes originate from only the heavy atoms then they are said to be isomorphous and can produce good estimates of phase. A difficulty of the method is that it requires trial-and-error testing to find compounds that bind tightly to the protein, while also achieving isomorphous diffraction. Experimental methods that rely entirely on anomalous dispersion effects are isomorphous and, despite providing a weaker signal, are intrinsically more accurate. These have proven to be very popular in recent times with the advent of synchrotron radiation sources and will be discussed in the next section.

MAD Phasing

Experimental phasing with multi-wavelength anomalous dispersion makes use of both anomalous differences (differences between Friedel pairs of reflections $\Delta_{\text{ano}} = |F(\underline{h})| - |F(-\underline{h})|$) and dispersive differences (differences between F values for a given reflection recorded at different wavelengths). The differences can occur only during inelastic scattering close to an atomic absorption edge. Anomalous dispersion effects can be modulated by varying the X-ray wavelength around the absorption edge. At the X-ray wavelengths normally used in diffraction experiments, most 'light' atoms (H, C, N, O, and S) scatter elastically. For most 'heavy' atoms, differences can be significant and are often sufficient to solve the phase problem. Selenium is particularly useful as proteins can be made in the presence of selenomethionine, which has the sulfur atom replaced with a selenium. The usual frequency of methionine is of the order of 1%, and a protein molecule may typically contain 2–20 methionine residues depending on its size.

For MAD phasing, it is essential to perform local scaling to ensure accurate differences between data measure at different wavelengths to calculate an unbiased estimate of the contribution from the heavy atom, $F_A(\underline{h})$. Direct and Patterson methods use these differences to determine the positions of heavy atom sites, which can then be refined and used for phase calculation. The phase calculation is performed in conjunction with the

refinement of the heavy atom substructure parameters (atom location, occupancy, and temperature factor) to give the most likely model and phase set. The phases may then be improved by means of density modification and extended to higher resolution beyond the initial heavy atom phasing.

A data collection technique may be employed to optimize absorption anomalous differences by measuring data in small wedges, interleaved with measurements taken at a 180° rotation offset to reduce the effects of absorption and crystal decay. A similar approach may be taken for optimizing dispersive differences, by measuring small wedges of data at different wavelengths. These methods are intended to minimize differences due to time-dependent fluctuations such as beam intensity fluctuations and radiation damage.

Although there are many packages available to assist in MAD phasing, of particular note are the SHELX tools (SHELXC/D/E), which give good results and are particularly quick. The PHENIX autosolve wizard provides more automated tools and includes local scaling, substructure determination, phasing, and phase improvement and requires little information other than the experimental data and a brief description of the experiment. Finally, autoSHARP is the tool of choice in difficult circumstances when data and model errors creep in and require a statistically unbiased approach to phase refinement. As with the PHENIX wizard, all steps are covered in this case by incorporating SHELX tools. An example of successful MAD phasing using Se anomalous dispersion phasing is shown in **Figure 3**.

SAD Phasing

Although the underlying principles of SAD phasing are similar to those of MAD, only one set of anomalous differences is available, resulting in phase ambiguity: for each reflection, two phases are possible as the sign of the phase is unknown. Because of this, phase improvement plays an essential role in breaking this ambiguity. Either a high solvent fraction or a high-resolution data are necessary for successful phasing. There are, however, many benefits to SAD phasing. First, it may be possible to determine the structure from a single data set, thus avoiding scaling problems. Second, data collection and data reduction are more straightforward. It is remarkable to observe that in favorable circumstances, it is possible to accurately phase a data set from anomalous differences that can be as small as 5% of the mean amplitude. A diagrammatic scheme of SAD phasing is shown in **Figure 4**.

Of particular interest is the use of naturally occurring sulfur atoms for the phasing, from cysteine and methionine residues. At typical synchrotron wavelengths (~ 1 Å), the anomalous difference is very small, requiring exceptionally high-quality data. At longer wavelengths

Figure 3 The crystal structure of fumarase from *Archaeoglobus fulgidus* at 1.66 Å resolution. Structure determined by the Joint Center for Structural Genomics (JCSG), to be published (PDB code: 2isb). Crystals were grown from 0.2 M Li acetate, 20.0% PEG 3350 at pH 7.8 in nanodrops by vapor diffusion. MAD data sets were collected on the ALS synchrotron source using an ADSC 210 CCD detector at wavelengths 1.0000 and 0.9796 Å around the Se absorption edge. A total of 9 SeMet sites were used for phasing. The image shows the automatically traced model fitted into the electron density map calculated with experimentally determined phases and observed amplitudes from Phenix (autosolve).

(~2 Å), the signal becomes more appreciable, making S-SAD phasing a reality, but at the cost of increased absorption and air scatter. As with any SAD phasing problem, a high solvent fraction, high-resolution data, and NCS averaging of a number of molecules are essential.

Molecular Replacement

The principle behind molecular replacement is to use a known structure, which is believed to be similar to the unknown macromolecule, to calculate an initial set of phases. To do this, one or more copies must be correctly rotated and translated, based on a comparison of the calculated and observed structure factor amplitudes. It is important to note that accurately measured low-resolution data (<4 Å) is critical to the success of molecular replacement searches.

The first step in the molecular replacement process is the choice of a model structure. In some circumstances this will be trivial, for example, in ligand-binding studies or when investigating point mutations. In most cases, however, it will be necessary to perform a search of a

Figure 4 A graphical description of the SAD phasing method. The observed measurements are the measured amplitudes F_{ph} and anomalous differences $\Delta_{ano} = |F_{ph}(h)| - |F_{ph}(-h)| = |F_{ph}(+)| - |F_{ph}(-)|$. The measured amplitude $|F_{ph}(h)| = (|F_{ph}(h)| + |F_{ph}(-h)|)/2$ originates from protein and heavy atom scattering such that the vector sum is $F_{ph} = F_p + F_h$. Close to their heavy atom absorption edge, the atomic scattering factors are modulated by dispersive and absorption terms ($|F_A| = |f_o + \delta f' + i f''|$). In an SAD experiment only f'' is used, whereas in an MAD experiment $\delta f'$ can also be used. (a) The vector diagram relates F_p , F_h , $F_{ph}(+)$, and $F_{ph}(-)$. Only structure factor amplitudes $F_{ph}(+)$ and $F_{ph}(-)$ are measured, whereas F_p and F_h are unknown. Heavy atoms can be located by Patterson synthesis or direct methods and the vectors F_A and $2f''$ calculated. (b) The phase circles for $F_{ph}(+)$ and $F_{ph}(-)$ are centered at either end of the vector $2f''$ and represent the uncertainty of the phase Φ_{ph} . The intersection of the circles provides two solutions of the phase problem, but only one is correct. The ambiguity can be resolved by density modification methods such as solvent flattening, histogram matching, or molecular averaging.

suitable 3 D model in the Protein Data Bank (PDB) based on the putative sequence. The results of this search may be further modified, for example, removal of non-conserved residues with the program 'chainsaw.'

Although the search is strictly 6D (three rotations and three translations for each molecule), it is usually divided into separate rotation and translation searches, leading to a massive reduction in the search space. The result of this search is a model that may be either used for calculation of an initial set of phases to be improved with density modification or taken as a starting point for refinement. Although there are a number of molecular replacement programs available, Phaser uses the most sophisticated scoring method that combines a high degree of automation with maximum likelihood-based scoring of potential solutions, and is particularly well suited to multiprotein complexes. For straightforward cases, programs such as Molrep may give a perfectly good result much more quickly.

The whole process can be performed automatically with MR Bump, which incorporates a number of MR programs. This will search the PDB database based on the results of several sequence searches and generates a list of possible search models. Molecular replacement searches are then run with each model and the results scored by the refinement of the solution. In challenging cases, the brute force nature of this search process may be beneficial.

Direct Methods

The use of direct methods for *ab initio* determination of macromolecular structures has been limited to molecules with ~2000 nonhydrogen atoms and data at high resolution, <1.2 Å. However, these methods have been useful for augmenting other phasing methods that will be explored in this section. The foundations of direct methods are the linear phase combinations of phases called structure invariants, of which the most useful are the triplet invariants that relate three amplitudes and their phases.

$$\Phi_{HK} = \varphi_H + \varphi_K + \varphi_{-H-K} \quad [5]$$

The triplet phase obeys the conditional probability distribution:

$$P(\Phi_{HK}) = [2\pi I_0(A_{HK})]^{-1} \exp(A_{HK} \cos \Phi_{HK}) \quad [6]$$

$$A_{HK} = (2/N^{1/2}) |E_H E_K E_{H+K}| \quad [7]$$

where E is a normalized structure factor and H and K are vector indices that satisfy the three reflection relationships. I_0 is the zeroth order-modified Bessel function and N is the number of identical atoms in the structure. These estimates are reliable when the structure factor amplitudes are large. The tangent formula is used when a sufficiently

large number of phase pairs are known.

$$\tan(\varphi_H) = - \frac{\sum_K |E_K E_{-H-K}| \sin(\varphi_K + \varphi_{-H-K})}{\sum_K |E_K E_{-H-K}| \cos(\varphi_K + \varphi_{-H-K})} \quad [8]$$

The method, as implemented in SHELXD, is of most use in determining substructures of heavy atoms in MAD or MIR data by using normalized isomorphous or anomalous differences as the structure amplitudes. An extension of the substructure approach is implemented in ACORN, which locates the positions of fragments or domains by molecular replacement methods that are then used to calculate a starting phase set that can be expanded and improved by direct method techniques. The robustness of the method depends on a combined powerful figure of a merit scoring system that discriminates between correct and incorrect phase sets.

Electron Density Improvement

Nearly always, experimentally determined phases are improved by density modification methods that use various assumptions about the electron density map that place limits on the observed starting phases. A map is modified and new phases generated by inverse Fourier transformation (eqn [2]). The process is iterated until some convergence is achieved. The method can be used to estimate phases and amplitudes for unmeasured reflection and to extend phases to high resolution where only amplitudes exist. There are a number of algorithms for improving electron density that can be used separately or in combination. The most common are solvent flattening, histogram matching, and molecular averaging, although the last-mentioned requires more than one copy of a molecule in the asymmetric unit. Less common is the use of direct method phasing in the form of Sayre's equation. Macromolecular crystal structures typically contain solvent in the region of 30–70%, and solvent flattening exploits the observation that electron density, in these regions, is flat due to high thermal motion and disorder of solvent molecules. Peaks in this region are assumed to originate from noise and are eliminated by fixing solvent regions to a mean constant value. The frequency of electron density distribution is a characteristic of the atomic distances within a macromolecule, and histogram matching can be understood as a quantitative description of a map that has the appearance of protein electron density. The electron density can therefore be modified to follow the expected distribution. In many cases, macromolecules crystallize as a number of molecules in the asymmetric unit. This is called non-crystallographic symmetry (NCS) and obeys local symmetry in addition to the rules of crystal symmetry. An example can be an oligomeric complex with the NCS axis at some random orientation. The procedure is to

average identical copies of electron density and in so doing increasing the signal-to-noise ratio of the electron density. Sayre's equation is very powerful for phase refinement at very high resolution but less useful at medium resolution, but it can still be effective, providing the shape function $\theta(b)$ can be modified to model the overlap of atoms at nonatomic resolution.

$$F(H) = [\theta(H)/V] \sum_k F(K)F(H-K) \quad [9]$$

The estimated phases can be used to augment experimental phases with σ_A weighting and combined with other density-modified procedures.

Structure Refinement

Refinement of a macromolecular model relies on the agreement between the calculated and observed diffraction pattern amplitudes. The process is complicated by a model containing thousands of atoms, which is refined against a data set comprising $\sim 100\,000$ measurements. The refinement process is intimately connected to the model building during which new features are identified and added into the refinement steps. At lower resolution, when the number of refined parameters may outnumber the measurements, it is essential to use chemical restraints to augment measurements, or alternatively chemical information can be used as a constraint to reduce the number of parameters. Only at atomic resolutions ($<1.2\text{ \AA}$) is it feasible to perform unrestrained refinement, although in practice the weight between the contributions is modified in favor of amplitudes. A more robust method of refinement, and one that is mostly used, is to maximize the probability that a model is correct (maximum likelihood) in the form of the sum of logarithms rather than least-squares refinement. The simplest parameterization is to refine coordinates and a thermal parameter for each atom. If the resolution is sufficiently high, it is possible to refine six anisotropic thermal parameters. However, macromolecular atomic motions can be highly correlated, and an alternative approach is group anisotropic TLS refinement, where a 20-term tensor models translational, rotational, and screw motions and has proven useful for large domain motion refinement. If atomic coordinates are significantly away from their refinement, minimum convergence of refinement can be

improved by employing simulated annealing, which increases the number of sampling points with molecular dynamics algorithms that perturb the structure. With sufficiently high-resolution data, model building is done automatically coupled to refinement cycles by programs like APR/wARP. If this is not possible, a model-building program like O or Coot must be used for manual building followed by rounds of structure refinement. Ultimately a validation of the structure is required through acceptable R-factors (15–25%), between observed and calculated structure factor amplitudes, while ensuring that the free R-factor, calculated with a small proportion of reflections not included in refinement, continues to fall. At the same time, the geometry of the structure must fall within accepted bounds with respect to the Ramachandran torsional angles, bond distances, and angles. The most commonly used refinement programs are Refmac5, CNS, and Buster-TNT. All use maximum likelihood refinement methods.

Overview

Spectroscopic measurements are at the heart of many analytical procedures and processes. Proper and adequate calibration and qualification of spectrometers are an essential part of the process for ensuring data integrity. Wherever practicable, the standards used should be traceable to a recognized national or international standard. The International Organization for Standardization (ISO) 9000 series of standards are the international metrics for quality systems.

Quality of measurement is central to compliance: for example, ISO 9000:2008 Section 7.6, Control of monitoring and measuring devices, requires that:

... Where necessary to ensure valid results, measuring equipment shall... be calibrated or verified at specified interval, or prior to use, against measurement standards traceable to international or national standards; where no such standards exist, the basis for calibration or verification shall be recorded.

More detailed information on the compliance requirements for the competence of calibration and testing laboratories is contained in ISO/IEC 17025 standard. Many laboratories seek accreditation to this standard and operate quality and testing systems that meet the

requirements. The ISO/IEC 17025 standard approach focuses heavily on good analytical practices and adequate calibration of instruments with nationally or internationally traceable standards wherever possible.

In addition to the ISO approach, environmental measurements (e.g., by the US Environmental Protection Agency) and the pharmaceutical industry are subject to rigorous regulatory requirements. The pharmaceutical industry has placed great emphasis on method validation in, for example, HPLC. However, until recently, there has been little specific regulatory guidance for assuring that the analytical instruments are working properly. In 2008, specific guidance on analytical instrument qualification was published in US Pharmacopoeia (USP) General Chapter <1058>. Recently, the USP has announced that its Reference Standards Laboratory has been certified to ISO Guide 34:2000 – General requirements for the competence of reference material producers.

In the United States, there is a specific legal requirement in the Good Manufacturing Practice Regulations for pharmaceuticals (21 CFR 211 §211.160) that requires:

The calibration of instruments, apparatus, gauges, and recording devices at suitable intervals in accordance with an established written program containing specific directions, schedules, limits for accuracy and precision, and provisions for remedial action in the event accuracy and/or precision limits are not met.

Instruments, apparatus, gauges, and recording devices not meeting established specifications shall not be used.

‘Fitness for purpose’ is the commonly used phrase.

Only the pharmacopoeias (e.g., the USP and the European Pharmacopoeia) have been sufficiently concerned by instrumental factors to give written requirements for instrument performance. Although these guidelines are not entirely consistent, at least they are attempting to ensure consistency of calibration practices between laboratories.

Table 7 Nuclear magnetic resonance (NMR)

<i>Monograph</i>	<i>Authority</i>	<i>Test</i>	<i>Standard</i>	<i>Measurement process</i>	<i>Acceptance criteria</i>
NMR	Ph. Eur. Method 2.2.33	Resolution	20% v/v 1,2-dichlorobenzene in deuterated acetone	Peak width at half the height of the band at δ 7.33 or δ 7.51 ppm of the symmetrical multiplet for dichlorobenzene.	Less than or equal to 0.5 Hz
			5% v/v tetramethylsilane in deuteriochloroform	Peak width at half the height of the band at δ 0.00 ppm for tetramethylsilane.	Less than or equal to 0.5 Hz
		Signal-to-noise (SIN) ratio	1% v/v ethylbenzene in carbon tetrachloride	Measure the spectrum over range δ 2–5 ppm. Measure the peak amplitude, A , of the largest peak of the methylene quartet centered at δ 2.65 ppm and the peak-to-peak amplitude of the baseline noise between δ 4 and δ 5 ppm. The amplitude is measured from a baseline constructed from the center of the noise on either side of the quartet and at a distance of at least 1 ppm from its center. H is the peak-to-peak amplitude of the baseline noise.	The SIN ratio is given by $2.5 (A/H)$, which has to be greater than 25:1 for a mean of five successive measurements
		Side-band amplitude			Amplitude of spinning side bands is not greater than 2% of the sample amplitude at the rotational speed used
		Integrator response repeatability	5% v/v ethylbenzene in carbon tetrachloride	For quantitative measurements, carry out five successive scans of the protons of the ethyl groups and determine the mean values.	No individual value shall differ by more than 2.5% from the mean

However, there has been a resurgence of interest in the underlying data quality by regulatory authorities, particularly the Food and Drug Administration (FDA), following a major legal ruling involving Barr

Laboratories, Inc., in 1993. This case changed the regulatory focus and put the laboratory firmly in the spotlight in terms of the assurance of the quality of the data it produces.

Table 8 Circular dichroism (CD)

Monograph	Authority	Test	Standard	Measurement process	Acceptance criteria
CD	Ph. Eur. Method 2.2.41	Absorbance accuracy	1.0 mg ml ⁻¹ isoandrosterone in dioxan (a solution of (1 <i>S</i>)-(+)-10-camphorsulfonic acid in water).	Record the spectrum between 280 and 360 nm and determine the maximum at 304 nm.	$\delta\epsilon$ is +3.3
		Linearity of modulation	Dissolve 10.0 mg of (1 <i>S</i>)-(+)-10-camphorsulfonic acid in water and dilute to 10.0 ml with the same solvent. Determine the exact concentration of camphorsulfonic acid in the solution by ultraviolet spectrophotometry, taking the specific absorbance to be 1.49 at 285 nm. (1 <i>S</i>)-(+)- or antipodal (1 <i>R</i>)-(-)-ammonium 10-camphorsulfonate can also be used.	Record the spectrum between 185 and 340 nm and determine the maxima at 192.5 and 290.5 nm.	At 192.5 nm, $\delta\epsilon$ is -4.3 to -5, At 290.5 nm, $\delta\epsilon$ is +2.2 to +2.5

Up to this point, the focus has been on the spectrometer and the underlying data quality. However, from an analytical science perspective, process is important, as illustrated in **Figure 1**. Scientific knowledge is founded on relevant and robust information generated from reliable data.

Quality has to be built in at all stages of the process, for failure to ensure integrity at any level invalidates results from further processing. One of the key areas not covered by this article is the validation of the software and systems involved in instrument control and data transformation. Clearly, this must be addressed as part of the overall assessment for the 'fitness for purpose' of any computerized spectrometer.

This article is restricted to the calibration requirements for spectrometers within the regulatory context, which, from a practical standpoint, means the major pharmacopoeias.

Spectroscopic Coverage

Current spectrometric monographs include calibration requirements for infrared (IR), near infrared (NIR),

ultraviolet and visible (UV-visible), nuclear magnetic resonance (NMR), circular dichroism, and polarimetry. Monographs for atomic spectrophotometry, emission and absorption, fluorescence, and X-ray fluorescence are available in the European Pharmacopoeia but do not specify calibration requirements other than that they are to be operated in accordance with the manufacturer's instructions. A series of ASTM standards are available and are listed in **Table 1**. Although primarily intended for use by instrument vendors and for instrumental fitness for ASTM analytical procedures, they are sometimes useful in supplementing pharmacopoeial guidance.

Tables 2–8 summarize the current requirements of the European Pharmacopoeia (Ph. Eur.) and the US Pharmacopoeia (USP).

Introduction

Carbohydrates, the most widely abundant biological molecules, are key components within a wide variety of biological phenomena. Polysaccharides such as glycogen, cellulose and starch have important structural or nutritional roles, but it is the mediation of specific recognition events by carbohydrates that has sparked detailed analyses of structure, conformation and function. The non-invasive, non-destructive nature of the technique is commonly mentioned as the most important reason for analysing carbohydrates by NMR and is of considerable advantage when dealing with small amounts of precious material. This advantage is, however, offset by the relative insensitivity of the technique when compared with other methods such as mass spectrometry or enzymatic approaches that may be more appropriate for specific problems of sequence determination or compositional analysis. The value of NMR analysis is apparent in the additional data obtainable regarding composition, structure, conformation and mobility necessary for understanding recognition processes. The analysis of carbohydrates by NMR is characterized by a modification of existing techniques to address the particular problems of oligosaccharide spectra, namely poor dispersion, heterogeneity, a relatively high degree of interresidue mobility and a lack of conformational restraints.

This article will attempt to provide an introduction to a large field of study, and readers are encouraged to look to the Further Reading section for additional information.

Sample Preparation

In high-field NMR, the use of high-quality sample tubes can have a significant impact upon the quality of the spectra.

For biologically relevant NMR analysis, experiments are generally carried out in aqueous solution. A strong water signal prevents direct analysis of proton signals lying beneath it and, owing to the problems of dynamic range, would reduce the sensitivity with which weak solute signals are detected. If, as is often the case, the exchangeable OH or NH protons are not of interest, then experiments are usually carried out in $^2\text{H}_2\text{O}$. Repeated dissolution and evaporation or lyophilization is recommended to reduce the proportion of residual protons remaining. In most cases, two dissolutions into $>99.8\%$ $^2\text{H}_2\text{O}$ followed by a final dissolution into $>99.95\%$ $^2\text{H}_2\text{O}$, preferably from a sealed ampoule, should be sufficient. Other precautions such as pre-wetting pipettes, further rounds of dissolution and drying, or the use of a dry box may be used for greater sensitivity or quality.

Although extremes of pH or pD (outside the range δ 5–8) are to be avoided, buffer solutions are only necessary in two cases: if the molecule is charged and the charge state is relevant to the study; and in the study of acid-labile carbohydrates, such as sialylated oligosaccharides.

The use of $^1\text{H}_2\text{O}$ as solvent is necessary in some cases and requires appropriate water suppression techniques. Care must be taken to ensure that the water is free from impurities as well as dissolved gases or paramagnetic species. A deuterated solvent to provide an appropriate lock signal should be added, usually 5–10% $^2\text{H}_2\text{O}$.

Oligosaccharides are not normally soluble in non-aqueous solvents, except for dimethyl sulfoxide (DMSO). Despite the biologically irrelevant environment, this permits the observation of exchangeable protons, and there is also some increase in the proton spectral dispersion. Similar precautions to those noted for the use of $^2\text{H}_2\text{O}$ should be observed, such as the use of high isotopic purity ($>99.96\%$) solvent and repeated dissolution to remove exchangeable protons.

To approach optimal line widths, it is often advisable to remove soluble paramagnetic components by passage through a suitable chelator. Degassing to remove

dissolved oxygen is also recommended. For acceptable spectra within a reasonable time using a 500 MHz spectrometer, 10 nmol is an approximate lower limit for 1D ^1H spectra; for 2D ^1H spectra, amounts of 1 μmol are preferable, although spectra with as little as 100 nmol are possible with care. Sample volumes vary between 0.4 and 0.7 ml, depending on the size of the spectrometer RF coils. Temperature should be maintained at a constant level, preferably one or two degrees above room temperature for stability. Sample spinning is not necessary, except in cases where resolution is a particular problem. T_1 for protons in carbohydrates is of the order of 0.1–0.5 s, and recycle delays of 1–1.5 s are usually sufficient.

Referencing of samples is commonly to acetone at δ 2.225 relative to DSS (5,5-dimethylsilapentanesulfonate) at 25 °C, or DMSO at 2.5 ppm.

Analysis of Carbohydrate Structure by NMR

The problems of carbohydrate structure addressed by NMR can be divided into four parts:

1. What is the composition of the molecule: what monosaccharides are present, are they in furanose or pyranose configurations, and α or β anomeric forms?
2. What is the nature of the linkages between the monosaccharides: at what positions do the substituents occur, and in what sequence?
3. What is the conformation of the molecule: what conformation or family of conformations are populated about the O-glycosidic bonds and hydroxymethyl rotamers?
4. What are the dynamic properties of the molecule?

Whilst the first and second questions can be satisfactorily answered by NMR, they are perhaps better approached in tandem with chemical or enzymatic methods, such as hydrolysis, followed by reduction and analysis of alditol acetates by GC-MS, or digestion with specific glycosidases. Such a concerted approach has been used to successfully determine the composition and configuration of many oligosaccharides and glycans.

The unique advantages of NMR in the analysis of carbohydrate structure are only fully apparent in consideration of points 3 and 4. In contrast to the unbranched polymeric nature of polypeptide and nucleic acid chains, carbohydrates may be branched structures, capable of substitution at several points. The monosaccharide constituents are polymerized in nature by a nontemplate directed, enzymatic process; the resulting oligosaccharides are often heterogeneous, differing in detail from a consensus structure. NMR is particularly efficient at investigating the solution conformations, and the dynamic properties of such molecules.

^1H NMR of Carbohydrates

Primary Analysis and Assignment: ^1H 1D Spectra

The ^1H NMR spectrum of the disaccharide galactopyranose β 1–4 linked to glucopyranose (Gal β 1–4Glc α , lactose, shown in **Figure 1**) is shown in **Figure 2**. Despite the relative simplicity of the molecule, with only 14 proton signals observable, the spectrum is surprisingly complex. This is due to the relatively small chemical shift dispersion of the non-exchangeable ring protons, resonating between δ 3 and 4. The small chemical shift dispersal combined with homonuclear spin–spin coupling gives rise in many cases to non-first-order spectra, complicating the measurement of spin-coupling values. This makes the assignment and analysis of even quite small saccharides quite difficult, and as a consequence the use of spectrometers of field strength 400 MHz or above is recommended.

Primarily owing to the electron-withdrawing effect of the ring oxygen, the anomeric (H1) protons give rise to signals lying outside this envelope of ring protons, between δ 4.25 and 5.5. Since equatorial protons experience a shift of approximately δ –0.5 relative to axial proton signals, α anomeric protons of D-sugars tend to be found between δ 4.9 and 5.5, and β protons between δ 4.3 and 4.7. The ring protons of each monosaccharide type give rise to characteristic patterns within the envelope of overlapping ring proton resonances. However, incorporation of a monosaccharide residue into an oligosaccharide will cause changes in these chemical shift patterns. For example, substitution at a given carbon causes the signal arising from the attached proton to change by δ 0.2–0.5.

The glucose residue of the sample shown in **Figure 2** is free to mutarotate between α and β forms. The signals arising from these are easily distinguished from those owing to the galactose H1 by the difference in area. The two glucose resonances have a combined area approximately equal to that of the galactose H1 resonance.

Anomeric signals typically exhibit characteristic doublets, arising from the $^3J_{\text{H-H}}$ H1–H2 coupling, whereas ring protons show more complex multiplet patterns. These

Figure 1 Structure of the disaccharide Gal β 1–4Glc α , showing the numbering of protons within the sugar rings.

Figure 2 ^1H 1D spectrum of the disaccharide galactopyranose β 1-4glucopyranose at 500 MHz and 303 K in $^2\text{H}_2\text{O}$. Peak assignments are given for well-resolved peaks, following the numbering of **Figure 1**. The unresolved proton 'envelope' consists of the remaining ring proton resonances. The peak marked 'HOD' arises from residual water within the sample.

Table 1 Structural reporter groups as described by Vliegthart and co-workers

Sugar type	Proton(s)	Parameter	Information content
All	H1	δ , J	Residue and linkage type
Mannose	H2, H3	δ	Substitution within core region of branched glycan
Sialic acid	H3	δ	Type and configuration of linkage
Fucose	H5, CH ₃	δ	Type and configuration of linkage: structural environment
Galactose	H4, H4	δ	Type and configuration of linkage
Amino sugars	N-acetyl CH ₃	δ	Sensitive to small structural variations

couplings are proportional to the dihedral angle between the two protons. Typical values for $^3J_{\text{H-H}}$ in carbohydrates are: axial-axial 7–8 Hz, axial-equatorial and equatorial-equatorial 3–4 Hz.

During the early 1980s, Vliegthart and co-workers identified a number of 'structural reporter groups', outlined in **Table 1**. Measurement of the chemical shift values, coupling patterns and line widths of signals arising from these elements can be interpreted to aid in the assignment and interpretation of 1D ^1H NMR spectra.

Sugar composition can thus be identified, and signals assigned on the basis of chemical shift and characteristic coupling values. The type and number of each can be established by consideration of chemical shifts, coupling patterns and relative integrals. Owing to the poor dispersion of the majority of resonances, this is usually

limited to resolved anomeric protons or other structural reporter groups. Despite the development of highly efficient experiments based upon the use of selective excitation to produce edited one-dimensional spectra with more manageable information content, full proton assignment usually relies upon two- or, in some cases, three-dimensional techniques.

Two-Dimensional Homonuclear Analysis

The poor dispersion and strong coupling present in carbohydrate proton spectra pose particular problems for the assignment process. In addition, the characteristics of a given spin system differ for each oligosaccharide and are highly dependant on structure. The use of two-dimensional experiments alleviates these problems.

Coherence transfer methods

The correlated spectroscopy (COSY) experiment reduces the degree of resonance overlap by separating resonances into two orthogonal proton dimensions. The 1D spectrum lies along the diagonal, with cross-peaks joining pairs of J -coupled spins. For carbohydrates, assignment can then start with the well-resolved anomeric protons, and continue by stepwise J -correlation to the remaining nuclei. This simple process is complicated in many cases by overlap and strong coupling between signals, even in two dimensions. To reduce these difficulties, high-quality spectra are needed, with optimal digital resolution.

Sometimes absolute value mode, as opposed to pure phase spectra, can be preferable for easy assignment, despite the theoretical disadvantages of a phase-twist line shape. Carbohydrate line widths are generally narrower than those of proteins and nucleic acids, and the use of absolute value spectra does not significantly diminish the quality of spectra, as seen in **Figure 3**. The COSY spectrum requires a pseudoecho weighting function to remove dispersive line shapes, reducing the sensitivity of the experiment. If sensitivity is an issue, then an inherently more sensitive experiment, such as the

absorption mode DQ-COSY (see following text) should be used.

If necessary, linkage positions can be identified using a COSY spectrum of a sample dissolved in DMSO- d_6 . The hydroxyl protons do not exchange with solvent, and they give rise to observable signals within the spectrum. Substitution removes the hydroxyl proton at that position, which can then be identified by the absence of a hydroxyl proton signal.

The COSY experiment may fail to generate the expected cross-peaks, for several reasons:

1. For strongly coupled neighbours, the cross-peak lies close to the diagonal and may not be seen.
2. Pairs of nuclei with small scalar coupling values ($^3J_{H-H}$) will produce low-intensity cross-peaks. Since the active coupling is antiphase in COSY cross-peaks, they will cancel if the value of J is less than the line width. This is particularly noticeable in larger molecules. Common examples are D-mannopyranose β H1-H2 ($J < 1$ Hz) and D-galactopyranose H4-H5 ($J < 1$ Hz).
3. Unrelated resonances may simply occur at the same position and cannot be distinguished.

Figure 3 ^1H - ^1H 2D COSY spectrum of galactopyranose β 1-4glucopyranose at 500 MHz and 303 K in $^2\text{H}_2\text{O}$. A full proton assignment is usually possible from a spectrum like this, and peak identities are shown where space permits. The well-resolved anomeric protons provide a useful starting point for assignment, and subsequent pairs of spin-coupled nuclei are correlated through off-diagonal peaks.

Experiments incorporating isotropic mixing sequences

The homonuclear Hartmann–Hahn (HOHAHA) experiment now also more commonly known as total correlation spectroscopy (TOCSY) is used to overcome problems of overlap and strong coupling. These experiments give correlations to all other spins within the same coupling network. The second pulse in the COSY sequence is replaced by a spin–lock sequence such as MLEV-17. The spin system becomes strongly coupled and coherence transfer occurs between all nuclei within the coupling network. This illustrates an advantage over experiments such as RELAY-COSY: values of $^3J_{\text{H-H}}$ between adjacent nuclei vary, and the use of an isotropic mixing period produces an increased efficiency of transfer. The presence of small couplings between nuclei, reducing the efficiency of transfer, still presents a problem.

Resolution in this type of experiment is better than for a COSY spectrum; however, more cross-peaks are generated, producing a more complicated spectrum. This is at first sight hard to interpret; however, proton assignments in each ring can be determined by inspection of a line lying through the frequency of the anomeric proton of the sugar residue. The cross-peaks found along this line can be distinguished by reference to the COSY spectrum, and by consideration of the multiplet structure. Pyranose rings have an effectively rigid ring geometry, and it is possible to estimate the couplings between adjacent protons based upon the dihedral angle between them. Judicious variation of the length of the isotropic mixing period can also be used to give stepwise correlations along the spin-system, since shorter periods correlate proportionately smaller fragments. One-dimensional analogues of this experiment, using selective pulses to specifically excite anomeric protons, may be quicker and more efficient, especially when the anomeric protons are well resolved.

Multiple-quantum homonuclear experiment

Incorporation of a multiple-quantum filter into a COSY-type sequence reduces the complexity of the spectrum, and aids in the assignment process.

A DQF-COSY, incorporating a double-quantum filter transparent to two or more coupled spins, therefore passes all signals except singlets. Such a sequence has a slightly reduced sensitivity (cross-peak intensity is approximately half that of a comparable COSY), but there is no need for the sensitivity-reducing weighting functions that are necessary with COSY. One noticeable feature is the absence of a diagonal, thus cross-peaks lying close to the diagonal can be more easily identified.

Incorporation of a triple-quantum filter produces a spectrum with signals due only to three or more coupled spins with two resolvable couplings. There are no singlets

or doublets, including anomeric resonances, although suppression is not absolute, due to the presence of small couplings along four or more bonds.

Under ideal conditions, one would expect to see resonances from only H5 and H6 protons, and this experiment is best used in conjunction with TOCSY for full assignment. Sensitivity is much reduced relative to COSY spectra.

Through-space dipolar interaction methods

Although primarily used for conformational analysis, the nuclear Overhauser effect spectroscopy (NOESY) experiment is also helpful in the assignment process. The resulting spectra show correlations between protons coupled by through-space dipolar interactions. Both inter- and intraresidue NOEs help to confirm the consistency of assignments made by the techniques described in the preceding text. Long-range NOEs are not often seen in carbohydrates, and the observation of NOEs between protons on adjacent residues is often evidence of the linkage positions between the two sugars.

Through-space dipolar interactions are of most use in the conformational analysis of biomolecules, as described in the section “Conformational analysis”.

At 500 MHz, moderate-sized (more than six residues) oligosaccharides lie within the spin-diffusion limit. However, for smaller molecules, as the value of the function $\omega_0\tau_c$ (where ω_0 is the Larmor frequency of protons, and τ_c is the correlation time of the molecule) approaches 1 then the value of the NOE tends towards 0. Cross-peak intensities of NOESY spectra of smaller oligosaccharides (2–5 residues) may thus become too small to measure accurately. In such cases, the rotating frame Overhauser effect spectroscopy (ROESY, originally referred to as CAMELSPIN) experiment is commonly used to measure NOE values. To reduce the appearance of TOCSY-like cross-peaks, a low power spin–lock field should be used, and the transmitter carrier offset to the low-field end of spectrum. The offset dependency of cross-peak intensities should also be removed by 90° pulses at either end of spin–lock period.

Three-dimensional experiments, often essentially hybrids of simpler sequences such as TOCSY-COSY, have been used successfully to resolve cases of particularly difficult resonance overlap.

Hydroxyl Protons

The quest for additional conformational information has led to the investigation of hydroxyl protons in aqueous solution. Samples are dissolved in mixed methanol–water or acetone–water solvents, and analysed in capillary NMR tubes at low (–5 to –15 °C) temperatures. Chemical exchange of hydroxyl protons is reduced to the point that it is possible to use them as probes of hydration

and hydrogen bonding. Distance information can also be extracted from NOESY or ROESY spectra under these conditions.

¹³C NMR of Carbohydrates

Primary Analysis and Assignment

Initial investigations of the ¹³C spectra of carbohydrates were of natural abundance samples, although spectra of isotopically enriched samples have become more common in recent years.

¹³C spectra are usually acquired with broad band proton decoupling. The resulting spectra are not very complex with, at natural abundance, a single sharp peak for each nucleus, there being no visible carbon–carbon coupling. The value of the carbon–proton coupling is approximately 150–180 Hz, and without proton decoupling this splitting, along with further two- and three-bond couplings, can render the spectrum quite complex.

Monosaccharides exhibit characteristic carbon chemical shift patterns. Anomeric carbons typically occur between δ 90 and 110 in pyranose rings, C6 (hydroxymethyl) signals between δ 60 and 75, and the remaining carbons resonate between δ 65 and 110. Substitution at a given carbon causes an approximate shift of up to $\delta + 10$. The usefulness of this shift in identifying the position of substitution is complicated by an additional $\delta -1$ to -2 shift of the surrounding carbon signals. In addition, the local structure of the saccharide can have a considerable effect upon the chemical shift values. Residue type and substitution patterns can thus be discovered, with care, from measurements of the carbon chemical shifts of a simple sugar. Databases of ¹³C chemical shift information for large numbers of simple carbohydrates are available for comparison in the literature.

Carbon–Proton and Carbon–Carbon Spin Couplings

A consistent estimate of the anomeric configuration is given by the value of the one-bond ¹*J*_{C–H} coupling; β anomers show a value of ~ 160 Hz, and α anomers ~ 170 Hz.

Three-bond carbon–proton scalar coupling values, such as ³*J*_{CCCH}, or ³*J*_{COCH} provide useful indicators of conformation. These couplings can be used to confirm the internal conformation of a saccharide residue, using appropriate Karplus curves. Across the glycosidic link, values of the couplings H1–C1–O–Cx (where x is the aglyconic carbon) and C1–O–Cx–Hx are proportional to the glycosidic dihedral angles ϕ and ψ , respectively (see section ‘Conformational analysis’). Selective incorporation of ¹³C has been successfully used to simplify and enhance the measurement of these parameters. Linkage positions can be unambiguously determined by the

identification of these couplings using experiments such as the 2D ¹³C–¹H multiple-bond correlation experiment (HMBC). This experiment correlates carbon and proton resonances by means of ³*J*_{C–H} couplings; ¹*J*_{C–H} correlations are suppressed, leaving only long-range couplings. Those couplings that span the glycosidic bond can thus be identified and measured.

Multidimensional, Heteronuclear Analysis

Enrichment with ¹³C allows the use of a wide range of useful experiments that greatly facilitate the investigation of carbohydrate structure. Proton detected versions of carbon–proton correlation experiments, such as that shown in **Figure 4**, overcome the sensitivity limitations of observing carbon signals. If the proton assignments are known, assignment of carbon resonances from such spectra is a relatively simple process. The use of carbon nuclei to edit spectra into an orthogonal frequency dimension to overcome overlap has led to the development of a series of useful hybrid 3D or pseudo-3D experiments, such as HCCH-COSY or HMQC-NOESY. Editing spectra in this way has helped to assign the spectra not only of complex glycans in free solution, but also of the attached carbohydrate chains of glycoproteins, both at natural abundance as well as enriched with ¹³C and ¹⁵N. The use of these heteronuclei allows the carbohydrate resonances to be observed separately from those due to the protein portion of the molecule.

Conformational Analysis

Measurement of ³*J*_{H–H'} couplings shows that pyranose rings do not show any large degree of internal flexibility, except for pendant groups such as the hydroxymethyl in hexopyranoses. Interpretation of these uses the Haasnoot parametrization of the Karplus equation for ³*J*_{H–H} couplings in HCCH portions of the saccharide ring:

$$^3J_{H-H'} = 13.22\cos^2\theta - 0.99\cos\theta + \sum_i \Delta\chi_i[0.87 - 2.46\cos^2(\xi_i\theta)] \quad [1]$$

where θ is the HCCH' torsion angle, $\Delta\chi_i$ are the Huggins' electronegativities of the substituents relative to protons and ξ is either $+1$ or -1 depending upon the orientation of the substituent. If stereo-specific assignments have been made, orientation about hydroxymethyl rotamers can be determined by similar parametrizations.

Conformational variability in pyranoside oligosaccharides is mostly owing to variations about the glycosidic torsion angles ϕ and ψ and, for $1 \rightarrow 6$ linkages the ω angle (**Figure 5**). NMR analysis of carbohydrate conformation thus concentrates upon determining the orientations about these dihedral angles. This is made difficult by the lack of conformational information

Figure 4 HSQC ^1H – ^{13}C correlation spectrum of galactopyranose β 1–4glucopyranose at 500 MHz and 303 K in $^2\text{H}_2\text{O}$. Resonances are labelled with the appropriate assignment for each correlation. In practice, these can be relatively easily identified by comparison with previously assigned proton or carbon chemical shifts. Reproduced by courtesy of Homans SW and Kiddle GR, University of St. Andrews.

Figure 5 A 1→6 linked disaccharide showing the dihedral angles ϕ , ψ and ω , about which conformational variation is greatest.

available: even in the most favourable conditions, a maximum of around three NOEs are seen between each pair of residues in oligosaccharides, and observation of long-range correlations between different parts of the molecule is extremely unlikely.

Interresidue correlations in NOESY or ROESY spectra can be used to determine distance information by making use of the fact that the intensity of the cross-peak is proportional to the inverse sixth power of the distance between the two nuclei. The relatively inflexible ring

geometry of pyranose rings allows intraresidue NOEs to be used to calibrate adjacent intraresidue correlations. When implementing such experiments it is important to ensure that the initial rate approximation holds. The motion of the molecule, both internal and overall, also affects the intensity of the NOE; thus interpretation of NOE values must take into account the motional model used. Since it is now clear that the majority of carbohydrate structures are flexible to some degree, oscillating through an ensemble of related conformations, this can be a problem. Flexibility is understood to be particularly marked about 1→6 linkages owing to rotation about the additional dihedral angle, ω .

The use of three-bond $^3J_{\text{C-H}}$ couplings as conformational probes has been described, using the Tvaroska parametrization of the Karplus relationship:

$$^3J_{(\text{C,H})} = 5.7\cos^2\theta - 0.6\cos\theta + 0.5 \quad [2]$$

where θ is the HCOC torsion angle. However, in a similar situation to that described for NOE restraints, these analyses have been hampered by the extent to which these values are subject to conformational averaging. Because of these problems, angular information derived from $^3J_{\text{C-H}}$ values is perhaps better used for evaluating the quality of conformational ensembles.

More recent work has addressed the use of ^{13}C within isotopically enriched compounds to derive additional conformational parameters, such as ^{13}C – ^{13}C scalar couplings, and ^{13}C – ^1H or ^{13}C – ^{13}C NOEs. These approaches have yielded useful results, but have been

hampered by the lack of a well-established Karplus-type relationship for ^{13}C – ^{13}C scalar coupling.

Investigators have thus made considerable use of theoretical methods such as molecular mechanics to complement the limited experimental data available.

Dynamics

The time-averaged nature of many NMR-derived parameters, and the degree to which it affects oligosaccharide conformations has made it necessary to attempt to measure the degree of mobility within oligosaccharides. Since the relaxation of protonated carbons is almost entirely due to the directly attached proton it is possible to measure relaxation parameters from them that are not affected by variations in internuclear distance. Investigation of carbohydrate dynamics has been approached by molecular modelling in combination with the measurement of relaxation rates, including the T_1 , T_2 of ^{13}C and ^1H , as well as ^1H – ^1H and ^{13}C – ^1H NOE values, to define the spectral density, given by

$$J(\omega) = \frac{(2/5)\tau_c}{(1 + \omega\tau_c)^2} \quad [3]$$

where τ_c denotes the rotational correlation time. These measurements have been interpreted by the Lipari–Szabo model-free approach, in which molecular motion is separated into overall and internal motions, related to the overall and internal correlation times τ_0 and τ_i :

$$J(\omega) = \frac{S^2(2/5)\tau_0}{(1 + \omega\tau_0)^2} + \frac{(1 - S^2)(2/5)\tau_i}{(1 + \omega\tau_i)^2} \quad [4]$$

where $1/\tau = 1/\tau_0 + 1/\tau_i$. S^2 is a measure of the degree of internal reorientation, varying in value from 0 for isotropic reorientation to 1 for no internal motion.

These measurements can then be used to derive dynamic models of carbohydrates and oligosaccharides. It is now generally accepted that carbohydrates are dynamic molecules with internal motions that occur on a time-scale faster than the overall motion of the molecules.

Application to Complex Carbohydrates

NMR spectroscopy has been applied extensively to the identification of complex carbohydrates of biochemical interest. These include bacterial cell wall capsular polysaccharides, complex polysaccharides from a variety

of plant origins, the branched oligosaccharides from glycoproteins, and lipid–sugar conjugates such as gangliosides and lipopolysaccharides. One active area of research is the study of carbohydrate–protein interactions, and here with a specific focus on cancer mechanisms, the conformational studies of glycoconjugates related to anti-tumour vaccines have been reported as well as the conformational analysis of glycosaminoglycans and their interactions, such as between heparin and fibroblast growth factor. For polysaccharide vaccines, NMR spectroscopy has been used as part of the quality control process.

As well as proving the identity of the individual sugar units and the various linkage positions, NMR spectroscopy can be used for the detailed study of molecular conformations through the interpretation of spin–spin couplings and nuclear Overhauser effects.

Introduction

Nuclear magnetic resonance (NMR) methods have become available to study metabolism and morphology at the cellular level. The NMR methods may be classified as magnetic resonance spectroscopy (MRS), magnetic resonance imaging (MRI) and combinations of both, magnetic resonance spectroscopic imaging (MRSI). MRS provides information on the chemical composition of cells and its changes under specific circumstances; MRI yields X-ray like images of cellular anatomy and physiology; MRSI can study the spatial distribution of some metabolites within large cells or cellular aggregates. Notably, most of the nuclei participating in cellular reactions or some of their isotopes are NMR active. This allows a large variety of cellular functions to be

monitored by different NMR methods. **Table 1** summarizes the magnetic properties of the nuclei most commonly used in NMR studies of cells as well as the biological information which can be obtained.

NMR studies of cells probably started in the mid 1950s analysing the dynamics of water in blood using ^1H NMR. However, modern NMR studies of cellular metabolism began later with the introduction of commercially available high-field spectrometers and Fourier transform NMR techniques. Improvements in signal-to-noise ratios allowed, in the early 1970s, a study by ^{13}C NMR of the metabolism of glucose in a suspension of yeast and to determine by ^{31}P NMR the intracellular pH in erythrocyte suspensions. Since then studies of cellular metabolism by NMR methods have been used routinely in many laboratories.

The development of cellular NMR is supported by some inherent advantages of the NMR method with respect to more classical approaches. First, the noninvasive character of NMR allows repetitive, noninvasive measurements of metabolic processes as they occur in their own intracellular environment. Second, the magnetic properties of nuclei like the relaxation times T_1 and T_2 or the homonuclear and heteronuclear spin coupling patterns contain unique information on the physiological or pathological status of the cells and on the flux through specific metabolic pathways. Third, NMR methods allow the acquisition of images of the spatial distribution of water in sufficiently large single cells or in cellular aggregates, and it seems likely that this approach will be extended to other metabolites in the near future. Despite these advantages, the NMR method is not devoid of drawbacks. In particular, NMR is a relatively insensitive technique with a metabolite detection threshold of around 10^{-1} mM for *in situ* cells and 10 μM in extracts for moderate-field spectrometers. Thus, to be able to obtain useful NMR spectra with an adequate signal-to-noise ratio, the cell cultures need to be grown to densities similar to those found in tissues. Even if cell extracts are used, these must be prepared from a sufficiently large number of cells to generate, in the NMR tube, metabolite concentrations in excess of the lower threshold for detection. These demanding conditions require the use of specialized perfusion systems for *in situ* NMR studies or

Table 1 NMR properties and type of biological information provided by various nuclei

Nuclei	Frequency (MHz)	Spin	Natural abundance (%)	Relative sensitivity	Information
^1H	400	1/2	99.98	1.0	Metabolite concentration. Cell fingerprinting. Flow through some pathways. Intra and extracellular pH. Cellular volume. Microscopic imaging. MRI
^{31}P	161.9	1/2	100	6.6×10^{-2}	Concentration of phosphorylated metabolites. Bio-energetic status. Intra- and extracellular pH. Cellular volume. Phospholipid metabolism
^{13}C	100.6	1/2	1.11	1.6×10^{-2}	Quantitative measurements of metabolic flow through specific pathways
^{23}Na	105.8	3/2	100	9.3×10^{-2}	Membrane potential. Cellular volume. Na^+/H exchange
^{19}F	376.3	1/2	100	0.83	Intra- and extracellular pH. Oxygenation state. Divalent metal ion concentration
^2H	61.8	1	0.016	9.7×10^{-3}	Lipid structure. Rates of hydration–dehydration reactions. Water flow and perfusion
^{39}K	18.7	3/2	93.1	5.1×10^{-4}	Membrane potential
^{17}O	54.2	5/2	0.037	2.9×10^{-2}	Water transport and metabolism
^{15}N	40.5	1/2	0.37	1.0×10^{-3}	Nitrogen metabolism
^{14}N	28.9	1	99.63	1.0×10^{-3}	Nitrogen metabolism

facilities for large-scale cell culture in work with cell extracts.

This article describes general procedures for cell culture compatible with NMR studies and illustrates the information that NMR methods can provide on cellular metabolism and morphology, with examples involving mainly the use of ^{31}P , ^{13}C and ^1H NMR. Several reviews, some of them quoted in the Further reading section, have covered this topic previously.

Large-Scale and High-Density Cell Culture Procedures Compatible with NMR Studies

The use of cell cultures provides a powerful tool to understand the cellular and molecular mechanisms occurring *in vivo*. Different types of cell culture exist depending on the origin of the cells used in the preparation. Primary cultures are obtained after enzymatic, chemical or mechanical disaggregation of the original tissue. Cell lines, transformed cells or cell strains are obtained from primary cultures after several passages from transplantable tumours or by cellular cloning. The *in vivo* behaviour is more closely resembled by primary cultures, but these usually require complex preparation resulting in relatively small cellular yields. Cellular lines or strains, and cellular clones have the advantage of being homogeneous cell populations that are easy to grow and maintain in large scale, but their behaviour is not as comparable to the *in vivo* situation.

Figure 1 illustrates the general procedure used to obtain a primary culture. The tissue of interest is dissected from the appropriate organ obtained from embryonic, newborn or adult donors. The dissected tissue is then chopped and disaggregated, digested enzymatically and the resulting cells are washed and collected by sedimentation. Cell counting and assessment of viability are easily accomplished later by optical microscopy, using a haemocytometer for cell counting and the dye exclusion criteria for viability assessment. The next step consists of cell seeding. Cells seeded normally attach to flat surfaces, grow, proliferate and differentiate until reaching confluence. Usually, NMR studies demand cell numbers in the range 10^7 – 10^8 cells, a quantity requiring a large number of culture dishes or flasks. To further increase the surface of the culture it is possible to use rollers. These devices allow cells to grow in the inner surface of a rolling cylinder which contains a moderate amount of culture medium. Several cylinders can be maintained rolling simultaneously in a rack, increasing enormously the surface area of the culture and thus the number of confluent cells. The excellent monograph of Freshney provides a more detailed description of every cell culture procedure and optimized techniques for particular cells.

There are two different kinds of experimental design in NMR studies of cells: (1) the study can be performed inside the magnet in real time, monitoring the metabolism of cells under *in situ* conditions; or (2) extracts can be prepared from the cells after different incubation times and examined by NMR under high-resolution conditions (**Figure 2**). In the first case special precautions need to be

Figure 1 General steps in the preparation of primary cell cultures.

Figure 2 High density cell culture devices compatible with *in situ* NMR spectroscopy. The tubes containing the entrapped cells can normally be accommodated in commercial high-resolution probes and placed inside the magnet (indicated by N and S).

taken to guarantee adequate nutrient supply, good oxygenation conditions and efficient removal of waste products from the NMR tube containing the cells. Different methods have been developed to fulfil these requirements. All of them involve a perfusion system adapted to the NMR tube which contains the cells immobilized or grown in different matrices. The perfusion system consists basically of a peristaltic pump, a thermostatically stabilized gas-exchange chamber or oxygenator and the NMR tube containing the cells. The peristaltic pump delivers fresh medium to the oxygenator and NMR tube and removes the used medium to a waste reservoir. The oxygenator is constructed of gas-permeable Silastic tubing equilibrated with an atmosphere of 95% O₂/5% CO₂. The NMR tube contains the entrapped cell suspension. There are basically three types of cell entrapment protocol compatible with NMR studies: (1) polymer threads, (2) microcarrier beads or (3) hollow fibre bioreactors.

Cells are entrapped in polymer threads (agarose or alginate) by mixing the cell suspension with a solution of the liquid polymer (above the gelling temperature) and extruding the mixture through a Teflon tube immersed in ice. The polymer solidifies at low temperature entrapping the cells in filaments which can be easily perfused. The advantage of this method lies in its simplicity, but on the other hand, cells are placed in a non-physiological environment. Alternatively, anchorage-dependent cells can be grown on the surface of solid or porous microcarrier beads of approximately 100 µm diameter. The beads can be made of different materials, and these include collagen, polystyrene, polyacrylamide, gelatine, and Sephadex. This method has the advantage that cells can be treated as a suspension. However, the density of cells may not be sufficiently high since most of the volume in the NMR tube is filled by the beads. The hollow fibre bioreactor approach consists of growing cells on the surface of capillary fibres which are gas and nutrient permeable. Cells are grown directly in a bioreactor adapted to the NMR tube where the experiment is performed, reaching higher density than with other methods. However, there are some technical difficulties in setting up this model properly, and it is relatively expensive. For a detailed description of the bioreactor approach, see the literature given in the Further reading section.

Applications

³¹P NMR of Cells

³¹P NMR spectra of cells show a small number of resonances but contain crucial information on cellular biochemistry and physiology. **Figure 3** depicts a representative ³¹P NMR spectrum obtained *in situ* from a

Figure 3 ³¹P NMR spectrum (161.1 MHz) of C6 glioma cells grown in a hollow fibre bioreactor. Note the important contribution of the GPC and GPE resonances. Reproduced from Inset: intra- (in) and extra- (ex) resonances of DMMP. From Gillies RJ, Galons JP, McGovern KA, et al. *NMR in Biomedicine* 6: 95–104, with permission from Wiley Limited.

culture of C6 glioma cells grown in a bioreactor. It is possible to distinguish clearly resonances from the β, α and γ phosphates of nucleotide triphosphates, phosphocreatine (PCr), phosphodiester (glycerophosphocholine, GPC, and glycerophosphoethanolamine, GPE), inorganic phosphate (P_i) and phosphomonoesters (PME). The resonances from the nucleotide triphosphates contain primarily (>90%) the contribution of MgATP and are normally referred to as ATP resonances. The PME peak is a composite resonance containing mainly contributions from phosphocholine (PCho) and phosphoethanolamine (PE), as well as from sugar phosphates in a smaller proportion.

³¹P NMR spectra provide quantitative information on the relative concentrations of phosphorylated metabolites. For spectra acquired under fully relaxed conditions, the area of the ³¹P NMR resonance is proportional to the concentration of the metabolite. Absolute quantifications are more difficult to perform but can also be obtained if the concentration of one of the phosphorylated metabolites in the sample (normally ATP) is measured by an independent method, such as enzymatic analysis. Unfortunately, the resonances from the α and β phosphates of ADP overlap under *in situ* conditions with those from the α and γ phosphates of ATP, thus precluding direct quantification of ADP *in situ*. The concentration of ADP *in situ* can be estimated indirectly from the difference in area between the α ATP or γ ATP peaks and the area of the β ATP peak, which is almost exclusively derived from ATP.

Probably, the main interest in ³¹P NMR spectroscopy lies in its ability to assess the bioenergetic status of the cell. This is determined by the relative rates of

ATP-producing and -consuming processes according to

In most mammalian cells, ATP is produced aerobically by oxidative phosphorylation and hydrolysed to provide the energy needed to support biosynthetic activities, maintain transmembrane ion gradients and perform cellular work. The balance between production and consumption of ATP determines its steady-state level and therefore the net availability for energy. If oxygen and nutrients become limiting, ATP synthesis may proceed for a short time using PCr as a phosphate donor in the following reaction:

Under these conditions no significant change occurs in the ATP resonances but a net decrease in the intensity of PCr is observed. When the ATP-buffering capacity of the PCr-creatine system is exceeded, net ATP hydrolysis occurs, resulting in a net increase in P_i and acidification, as described by eqn[1].

Another important aspect of ^{31}P NMR spectroscopy is that it allows the determination of intracellular and extracellular pH (in P_i -containing media) from the chemical shift of the P_i resonance. This is because P_i has an apparent pK_a of 6.7, and its chemical shift is pH-dependent in the physiological range. Normally, the chemical shift of the P_i resonance is measured with respect to internal references like PCr or α -ATP, which are nontitratable in the physiological pH range ($\text{pK}_a \approx 4.5$). The following expression can be used to measure intracellular pH from the chemical shift of $\text{P}_i(\delta)$ measured with respect to the α -ATP resonance:

$$\text{pH}_i = \frac{6.7 + \log(\delta - 11.26)}{(13.38 - \delta)}$$

The values 11.26 and 13.38 represent the acidic and alkaline limits of the P_i titration curve chemical shifts with respect to the α -ATP resonance. Phosphonic acid derivatives, like methylene diphosphonic acid (MDPA) or dimethyl methylphosphonate (DMMP), resonating far from physiological phosphates (c. 20–30 ppm) can be used as an external reference for chemical shift and concentration calibrations. Sometimes these references cross the cell membrane and two different resonances are observed for the intracellular and extracellular compounds. In these cases, it is possible to determine the relative cellular volume from the relative areas of the intra- and extracellular resonances (Figure 3 inset).

^{31}P NMR spectra also contain resonances from crucial phospholipid metabolites. These include the phosphodiester, glycerophosphocholine and glycerophosphoethanolamine and the phosphomonoesters, PCho and PE.

Tumoural cells and *in vivo* tumours show increased PME resonances, often caused by increased PCho content. This characteristic of tumour cells has been proposed to contain diagnostic or even prognostic information on tumours. The metabolic reasons underlying the increase in PCho in tumour cells are not completely understood but seem to be caused by an increase in its synthesis rather than to an increase in the degradation of phosphatidylcholine.

^{13}C NMR of Cells

^{13}C NMR spectroscopy allows the detection of resonances from ^{13}C , the stable isotope of carbon with a magnetic moment. The natural abundance for ^{13}C is only 1.1% of the total carbon and its magnetogyric ratio is approximately one-fourth of that of the proton. These two circumstances make ^{13}C NMR a relatively insensitive technique. However, this sensitivity problem can be improved by using ^{13}C -enriched substrates. The combination of ^{13}C NMR detection and substrates selectively enriched in ^{13}C have made it possible to follow *in vivo* and *in vitro* the activity of a large variety of metabolic pathways in cells and subcellular organelles. These include glycolysis and the pentose phosphate pathway, glycogen synthesis and degradation, gluconeogenesis, the tricarboxylic acid cycle, ketogenesis, ureogenesis and the glutamate, glutamine, γ -aminobutyric acid cycle in the brain among others.

The design of ^{13}C NMR experiments with selectively ^{13}C -enriched substrates is similar to the classical radiolabelling experiments using radioactive ^{14}C . A relevant difference is that ^{13}C precursors are used in substrate amounts, while ^{14}C substrates are normally used in tracer amounts. However, ^{13}C NMR presents important advantages over ^{14}C . First, the metabolism of the ^{13}C -labelled substrate can be followed in real time, *in situ* and noninvasively. Second, even if tissue extracts are prepared, the detection of ^{13}C labelling in the different carbon atoms of a metabolite does not require separation and carbon-by-carbon degradation of the compound, two normal requirements in experiments with ^{14}C . Finally, the analysis by ^{13}C NMR of homonuclear spin-coupling patterns and isotope effects allows the determination of whether two or more ^{13}C atoms occupy contiguous positions *in the same metabolite molecule*, a possibility only available to ^{13}C NMR methods. As a counterpart to these advantages, ^{13}C NMR is significantly less sensitive than other conventional metabolic techniques like radioactive counting, mass spectrometry or optical methods. In particular, ^{13}C NMR studies with cells *in situ* are difficult to find and most of the ^{13}C NMR work has been performed with cell extracts. This allows operation under high-resolution conditions and increases significantly both the sensitivity and the resolution.

Figure 4 Metabolism of $(1-^{13}\text{C})$ glucose in neural cells. HMP: hexose monophosphate shunt; TCA: tricarboxylic acid cycle; OAA: oxalacetate; α -KG: 2-oxoglutarate; GABA: γ -aminobutyric acid; Ac CoA: acetyl coenzyme A. Only one turn of the TCA is considered for clarity. Filled or open circles in TCA cycle intermediates indicate labelling from PDH or PC, respectively.

Figures 4 and 5 illustrate the use of ^{13}C NMR spectroscopy to study the metabolism of $(1-^{13}\text{C})$ glucose in primary cultures of neurons and astrocytes. A simplified scheme of the metabolism of $(1-^{13}\text{C})$ glucose in neural cells

is given in Figure 4. Briefly, $(1-^{13}\text{C})$ glucose is metabolized to $(3-^{13}\text{C})$ pyruvate through the Embden Meyerhoff glycolytic pathway. The $(3-^{13}\text{C})$ pyruvate produced can be transaminated to $(3-^{13}\text{C})$ alanine, reduced to $(3-^{13}\text{C})$ lactate

Figure 5 Proton decoupled ^{13}C NMR spectrum (125.7 MHz) of neutralized perchloric acid extracts obtained after the incubation of primary cultures of neurons (upper trace) or astrocytes (lower trace) with 5 mM ($1\text{-}^{13}\text{C}$) glucose during 24 h. 1: alanine C3, 2: lactate C3, 3: *N*-acetylaspatic C6, 4: acetate C2, 5: glutamine C3, 6: glutamate C3, 7: glutamine C4, 8: glutamate C4, 9: glutamine C2, 10: glutamate C2. An artificial line broadening of 1 Hz was used in both cases.

or enter the tricarboxylic acid (TCA) cycle through the pyruvate dehydrogenase (PDH) or pyruvate carboxylase (PC) activities. A net increase in ($3\text{-}^{13}\text{C}$)lactate reveals increased aerobic glycolysis and is normally observed under hypoxic conditions in normal cells. If ($3\text{-}^{13}\text{C}$)pyruvate enters the TCA cycle through PDH it produces ($2\text{-}^{13}\text{C}$)acetyl-coenzyme A first and subsequently ($4\text{-}^{13}\text{C}$) α -ketoglutarate. In contrast, if ($3\text{-}^{13}\text{C}$)pyruvate is carboxylated to ($3\text{-}^{13}\text{C}$)oxalacetate by PC, it will produce ($2\text{-}^{13}\text{C}$) α -ketoglutarate in the next turn of the cycle. The α -ketoglutarate–glutamate exchange is many times faster than the TCA cycle flux, and therefore ^{13}C labelling in the glutamate carbon atoms reflects accurately the labelling in the α -ketoglutarate precursor. Thus, ($4\text{-}^{13}\text{C}$)glutamate or ($2\text{-}^{13}\text{C}$)glutamate are produced from ($1\text{-}^{13}\text{C}$)glucose depending on the route of entry of the ($3\text{-}^{13}\text{C}$) pyruvate into the TCA cycle. Therefore, a comparison of intensities from the C4 and C2 glutamate resonances provides a qualitative estimation of the relative contribution of PDH and PC to the TCA cycle.

Figure 5 shows proton decoupled ^{13}C NMR spectra of perchloric acid extracts obtained from primary cultures of neurons (upper panel) and astrocytes (lower panel)

incubated for 24 h with 5 mM ($1\text{-}^{13}\text{C}$)glucose. The most relevant resonances are the ones derived from the C3, C4 and C2 carbons of glutamate; C3, C4 and C2 carbons of glutamine (or glutathione); C3 carbon of alanine; C3 carbon of lactate; C6 carbon of *N*-acetylaspatic acid and C2 carbon of acetate (see **Figure 5** legend for resonance assignments). The spectra of **Figure 5** reveal important differences in the metabolism of ($1\text{-}^{13}\text{C}$)glucose by neurons and astrocytes. Briefly, the lactate C3 resonance is higher in the spectrum of astrocytes than in that of the neurons. The glutamate C4 resonance is significantly larger in neurons than in astrocytes, while the C2 glutamine resonance in astrocytes is higher than in neurons. Taken together these results suggest that astrocytes metabolize glucose mainly through aerobic glycolysis having an important contribution from PC, while neurons metabolize glucose mainly through the TCA cycle, using PDH as the main route.

It is possible to obtain in cells quantitative determinations of flux through specific metabolic pathways or through specific steps of a pathway using ^{13}C NMR. There are two possible strategies, both based on the principles of isotopic dilution and both requiring the use

of mathematical models of metabolism. The first strategy allows the determination of fluxes by solving linear systems of equations relating flux to fractional ^{13}C enrichments in specific carbons of precursors and products. The second strategy involves the determination of relative isotopomer populations from an analysis of the ^{13}C - ^{13}C spin coupling patterns. For a more precise description of both methods, the reader is referred to the article of Portais and co-workers and Künnecke and co-workers in the Further reading section.

^1H NMR of Cells

^1H NMR has an inherently higher sensitivity than ^{31}P or ^{13}C NMR, and thus a larger number of metabolites potentially detectable. However, two limitations need to be considered: (1) the water signals from the cells need to be eliminated and (2) the complex homonuclear spin coupling patterns due to overlapping proton resonances have to be resolved. Both drawbacks have been overcome in part by the development of water suppression techniques and different one-, two- or n -dimensional editing methods.

The information provided by ^1H NMR spectra of cell suspensions is illustrated in **Figure 6** which shows a representative ^1H NMR spectrum of a suspension of rat erythrocytes acquired using a simple one-pulse sequence (**Figure 6b**). The most prominent resonances derive from the H3 proton of lactate, the choline protons of ergothioneine and the glutamate and glutamine resonances from glutathione. All these resonances are located on top of a much broader resonance arising from low-mobility lipids. Therefore, ^1H NMR spectroscopy allows lactate production to be followed easily. This is normally done using spin-echo sequences which eliminate the broad lipid component because of its short T_2 (**Figure 6a**). In addition to lactate, ^1H NMR normally allows the direct quantification of creatine singlets, singlets from choline-containing compounds and many other metabolites. Sometimes, quantification of these compounds requires very high resolution conditions, high spectrometer observation frequencies and computerized deconvolution algorithms. Indeed the ^1H NMR spectrum provides a true fingerprint of the metabolites present in the cell, and it appears to be characteristic for every cell type. This has been clearly shown in studies of cell typing with neural cells. Furthermore, it has been shown recently that fully transformed cells present an increase in the ^1H resonance of the PCho peak, and that the ratio PCho to GPC may serve as an indicator of multiple oncogene lesions.

A more recently developed application of ^1H NMR to cellular studies relies on the noninvasive determination of intra- and extracellular pH. The procedure is based in

Figure 6 ^1H NMR spectra (360.13 MHz) of a rat erythrocyte suspension in the presence of a ^1H NMR pH probe. The water resonance (not shown) was attenuated with a 2 s presaturating pulse. (a) Spin-echo acquisition with 5 ms interpulse delay. Inset: Expansion of the aromatic region. (b) Conventional one-pulse acquisition. Inset: Chemical structure of imidazole-1-yl acetic acid methyl ester, the pH probe used. a: TSP, b: lactate H3, c: glutamate H3, H3' in glutathione, d: aspartate H3, H3', e: creatine (methyl), f: trimethyl groups in choline, carnitine and ergothioneine, g: methanol, h: H2 of amino acids, i: lactate H2, k: H4 and H5 of the pH probe, l: H2 of the pH probe. H2i: intracellular probe, H2o: extracellular probe. Methanol is produced by endogenous esterases immediately after the addition of the probe.

the use of a probe containing a reporter proton with a chemical shift sensitive to pH in the physiological range. This method is inherently more sensitive than previous ^{31}P NMR approaches. **Figure 6a** illustrates more clearly this procedure by showing the spectrum of an erythrocyte suspension after the addition of the extrinsic pH probe imidazol-1-yl acetic acid methyl ester. The imidazole protons, H2 (c. 8.2 ppm) and H4, H5 (c. 7.25 ppm) are clearly observed in the aromatic region of the spectrum between 6 and 9 ppm (inset to **Figure 6a**). Two signals for the imidazole H2 proton (H2i and H2o) with different chemical shifts are observed. These signals have been shown to be derived from molecules of the probe located in the intra- (H2i) and extracellular (H2o) space. Thus, the different chemical shift of intra- and extracellular probes allows the determination of the intra- and extracellular pH values as well as the transmembrane pH gradient.

Figure 7 T_2 -weighted spin-echo microscopic ^1H NMR images (360.13 MHz) of an isolated neuron from *Aplysia californica* before (a) and after (b) hypotonic shock. Resolution (x, y, z) is $20\ \mu\text{m} \times 20\ \mu\text{m} \times 150\ \mu\text{m}$. Artificial sea water appears as a bright background surrounding the cell. T_2 differences between nucleus and cytoplasm cause these structures to appear as bright and dark, respectively. Reproduced from Hsu EW, Aiken NR, and Blackband SJ (1996) with permission of the American Physiological Society. *American Journal of Physiology* 271: C1895–C1900.

Finally, impressive progress in NMR microscopy methods has allowed the acquisition of ^1H NMR images of single cells. T_2 -weighted NMR images from single cells normally show a dark cytoplasm and relatively bright nucleus. **Figure 7** provides an illustrative example of cellular NMR imaging, showing the morphology of a neuron from *Aplysia californica* before (**Figure 7a**) and after (**Figure 7b**) hypotonic shock. The hypotonic shock increased the relaxation times T_1 and T_2 of cytoplasm and nucleus but did not change the apparent diffusion coefficient of water. In conclusion, ^1H NMR methods provide information on glycolysis, fingerprint cell typing, state of proliferation, intra- and extracellular pH and cellular micromorphology. Representative articles describing these ^1H NMR applications are given in the Further reading section.

Other Nuclei

In addition to the most commonly used nuclei, such as ^{31}P , ^{13}C and ^1H , other nuclei can be used in NMR studies of cellular metabolism (**Table 1**). The ^{19}F nucleus has a magnetic moment slightly smaller than ^1H , whereas its chemical shift range is larger by a factor of approximately 20. No contributions from tissue background signals are observed, which makes ^{19}F a useful magnetic label for metabolic studies. Using difluoromethylalanine or fluorinated derivatives of BAPTA, ^{19}F NMR spectroscopy has been extensively used to measure intracellular pH as well as cytosolic free Ca^{2+} and free Mg^{2+} in peripheral blood lymphocytes and other cells.

The ^{23}Na nucleus is a quadrupolar spin 3/2 nucleus with approximately 100% natural abundance. Because of its quadrupolar nature, some of the ^{23}Na is invisible to

the NMR experiment. However, it has been possible to resolve intra- and extracellular ^{23}Na resonances in yeast cells and erythrocytes and to monitor $\text{Na}^+ - \text{H}^+$ exchange in the latter cells.

The ^{17}O nucleus has an unfavourable gyromagnetic ratio but a large chemical shift range close to 1000 ppm. ^{17}O NMR has been used extensively to study water metabolism in erythrocytes and subcellular organelles.

Finally, ^2H is one of the most recent additions to the repertoire of cellular NMR methods. ^2H has a natural abundance of only 0.02%, and therefore the use of ^2H NMR requires the use of selectively enriched substrates. ^2H has been mainly used in cells to investigate the structure *in situ* of choline lipids in the cell membrane.

Introduction

EPR spectroscopy is a technique that affords a means for the detection and quantification of paramagnetism, i.e. the presence of unpaired electrons. It is applicable to solids, liquids or even gases. A compound or molecular fragment containing an odd number of electrons is paramagnetic. In this article we give examples to show the power and breadth of the technique. The reader is advised, however, to read the Encyclopedia article on the theoretical aspects of EPR to appreciate fully the strength of the technique and also the excellent series *Specialist Periodical Reports on Electron Spin Resonance*, published by the Royal Society of Chemistry, which has now reached volume 16.

The technique can be applied to obtain information on the following four areas.

1. How atoms are bonded together in molecules (structure).
2. The route by which compounds are transformed from one to another, i.e. which bonds break and which are formed (mechanism).
3. The rate at which these processes occur (kinetics).
4. The molecular interactions that exist, for example, between solvent and solute (environment).

Knowledge of the g values and the detailed hyperfine interactions (A values) allows us to help identify radical species, and these parameters contain information about

the electron distribution within the molecule. Radicals are often present as intermediates during a reaction; consequently their identification will give information concerning the reaction mechanism and measurement of how their concentration changes with time will give kinetic data.

Let us now look in greater detail at several major applications of the technique.

Organic and Organometallic Free Radicals; Structure, Kinetics and Mechanism

There are many examples of the power of the technique in this area and space does not permit us to cover fully all examples. Articles by Tabner and by Rhodes fully cover the basic principles and practical aspects for the detection and evaluation of radical anions and cations (see Further Reading). A comprehensive review of EPR methods and applications can be found in the series of books from the UK Royal Society of Chemistry entitled *Specialist Periodical Reports*, and this includes a whole series devoted to EPR spectroscopy, with the latest volume appearing in 2008, covering the literature from 2005 to 2006. Consequently we will select just one or two examples from these areas.

An early method, widely used for radical generation, is based on the redox system $\text{Ti}^{3+}-\text{H}_2\text{O}_2$. This was first used by Dixon and Norman to generate $\text{HO}^\bullet$ and $\text{HOO}^\bullet$ radicals obtained by rapid mixing of aqueous solutions of TiCl_3 and H_2O_2 with a substrate immediately before the EPR cavity. It has been suggested that the main reacting species in such a system is $\text{Ti}-\text{O}-\text{O}^{\bullet 3+}$. The EPR signals obtained from such a system depend upon such factors as flow rate, temperature, pH and the ratio of the two components. Flow systems such as this have been used quite successfully to study polymerization reactions that are initiated by redox reactions. Analysis of the hyperfine interactions of the reacting species enabled the structure of the radicals to be determined.

The use of such flow and/or stopped flow systems has been used quite extensively to investigate the kinetics of radical reactions. These include the use of a stopped flow EPR system to investigate the one-electron oxidation of a range of phenols by a dimeric manganese(IV/IV)

triazacyclononane complex with and without hydrogen peroxide.

Another use has been the development of a technique of photolytic time-resolved EPR that allows kinetic data to be obtained with relative ease. The method involves flowing oxygen-free solutions of the materials under investigation through a flat reaction cell placed within the EPR cavity. The flow rates of the solutions could be adjusted so that signal intensities were not dependent on their cavity dwell time. The solutions could be irradiated either continuously or intermittently and thermostatted by the use of a stream of dinitrogen. Signal averaging is used to overcome signal-to-noise difficulties.

Spin Trapping, Spin Labels and Spin Probes in Polymers and Biological Systems

The role of free radicals in biological and medicinal systems is of considerable interest as they have been implicated in a wide range of diseases such as cancer. In such systems, the direct detection of free radicals is often not possible because of their low steady-state concentration arising from their high reactivity and transient nature. In this instance, the technique of spin trapping is used. Spin trapping involves the addition of a diamagnetic molecule, usually a nitron or nitroso compound, which reacts with a free radical to give a stable paramagnetic spin adduct that accumulates until it becomes observable by EPR (eqn [1]).

[1]

By determination of the parameters of the spin adduct spectrum it is often possible to identify the nature of the primary trapped radical, or at least to determine the type of radical trapped. Table 1 gives examples of the range of hyperfine coupling constants obtained for a variety of trapped species for the two most commonly used spin traps DMPO (5,5-dimethyl-1-pyrroline *N*-oxide) and PBN (α -phenyl-*N*-*t*-butylnitron). Care has to be taken, however, because the coupling constants vary with solvent polarity (for example, in water the DMPO adduct of the *t*-butoxy radical has $a(\text{N})=1.48$ and $a(\text{H})=1.60$ mT while in toluene $a(\text{N})=1.3$ and $a(\text{H})=0.75$ mT).

The spin trap must react at relatively fast trapping rates and the radical adduct must have a reasonable half-life; for example, DMPO has a k_{trapping} for $\text{OH}^\bullet$ of $2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ and half-life of about 15 min, whereas for O_2^- , k_{trapping} is $1 \times 10^1 \text{ M}^{-1} \text{ s}^{-1}$ and the half-life is about 90 s. Consequently the DMPO- O_2^- adduct is

Table 1 Hyperfine coupling constants (mT) for a variety of spin-trapped adducts

Free radical	PBN		DMPO	
	^{14}N	^1H	^{14}N	^1H
$\bullet\text{H}$	1.53	0.82(2H)		
$\bullet\text{Phenyl}$	1.60	0.44	1.57	2.5
$\bullet\text{CCl}_3$	1.39	0.175		
$\bullet\text{OH}$	1.54	0.27	1.50	1.50
O_2^-	1.43	0.225	1.45	1.16
$\text{Bu}^t\text{O}^\bullet$			1.48	1.60
SO_3^-			1.47	1.60
$\text{PhS}^\bullet$			1.29	1.415

PBN, α -*t*-butyl- α -phenylnitron

DMPO, 5,5-dimethyl-1-pyrroline-*N*-oxide.

Table 2 Second-order rate constants for radical spin trapping for the traps PBN and DMPO

Spin trap	$R^\bullet$	T ($^\circ\text{C}$)	Rate constant ($\text{M}^{-1} \text{s}^{-1}$)
PBN	$\text{Me}^\bullet$	25	4×10^6
	$\text{RC}^\bullet\text{H}_2$	40	1.3×10^5
	$\text{Ph}^\bullet$	25	2×10^7
	$\text{HO}^\bullet$	25	2×10^9
	$\text{ROO}^\bullet$	60	1×10^2
DMPO	$\text{HO}^\bullet$	25	2×10^9
	O_2^-	25	1×10^1
	$\text{RC}^\bullet\text{H}_2$	40	2.6×10^6

rarely seen. This difficulty has been overcome by the use of phosphorus-substituted DMPO, in particular where one of the methyl groups in the 5 position has been replaced by a diethoxyphosphoryl group. This increases the half-life of the OOH adduct considerably in both organic and aqueous solvents, with the difference being more pronounced in aqueous solvents. One other advantage of the use of phosphorus-substituted DMPO spin traps is that the β - ^{31}P hyperfine coupling constant has a much larger variation (2.5–5.5 mT) than the β -H hyperfine coupling constant (0.6–2.5 mT), thus allowing an easier identification of the trapped radical.

Table 2 gives a range of bimolecular rate constants with both PBN and DMPO for a variety of radical species.

In a study of heterogeneous catalysis, the spin trapping technique has been used to prove the presence of radical species on a catalyst surface. In a study of a palladium metal catalyst supported on alumina, it was shown that hydrogen is dissociatively chemisorbed by trapping hydrogen atoms with PBN. Alkyl and aromatic

free radicals were also shown to be present when other feed stocks were used. In a separate study of the photodecomposition of acetaldehyde, it was shown that high-power irradiation (600 W mercury/xenon lamp) generated a different PBN adduct from that given with irradiation under direct sunlight and that the presence of oxygen played a major role in the photochemistry.

Since the first reported study on nitroxide spin labelling in 1965, the technique has found widespread application to biological and chemical problems. The introduction of a small free radical, the spin label, onto the molecule of interest gives environmental information at that point. It has the ability to measure very rapid molecular motion and is usually free from interference, thus making it a very powerful technique that gives useful details about dynamic processes at the molecular level.

The types of free radical mostly used as spin probes or spin labels are based on nitroxides, such as the label known as TEMPOL (4-hydroxy-2,2,6,6-tetramethyl-piperidinoxy). **Figure 1** shows the change in the EPR spectrum of a spin-labelled system going from a fully mobile isotropic system (**Figure 1c**) to a fully immobilized glass type spectrum (**Figure 1a**). Measurement of the hyperfine parameters enables information to be

obtained about the mobility or rigidity of the system under study.

The spin probe technique has been used to investigate the interactions of the anionic surfactant SDS and gelatin. It was found that for simple SDS solutions the rotational correlation time of the spin probe, 16-doxylstearic acid methyl ester, increased slightly with increased surfactant concentration. In contrast, in the presence of gelatin these properties varied markedly as a function of the stoichiometric ratio of the surfactant to gelatin concentration, with the correlation time decreasing as the hyperfine coupling constant increased with increasing surfactant concentration. Such behaviour was attributed to the characteristics of the various amino acids present in the gelatin.

The use of spin labelling in polymer systems has enabled information to be obtained about polymer chain size and also their conformational state, with three main states being distinguished. The ability of some nitroxide radicals to diffuse easily into various polymer systems, coupled with the fact that their EPR spectra with three lines caused by coupling to ^{14}N show a high degree of rotational motion in the amorphous parts of the polymer, means that studies varying the temperature through the glass transition temperature T_g will enable changes to be measured in the rotational correlation time. Since the rotational correlation time obeys the Arrhenius law (eqn [2]),

$$\tau = \tau_0 \exp(E_a/RT) \quad [2]$$

which is valid for $T > T_g$, values for the rotational activation energy of the nitroxide free radical can be measured. Since this does not depend on radical size but only on the polymer matrix, a measure of polymer mobility is obtained.

There are several excellent reviews on the application of the method to studies in polymer systems and also to investigations of biological membranes. These are listed in the 'Further Reading' section.

Study of Transition Metal Compounds

EPR spectroscopy is widely used to study the structure and geometry of d-transition metal ions (TMI) in inorganic complexes, in biological systems and in catalysts. Information obtained through analysis of the spectrum varies from simple identification of the metal centre to a thorough description on the electronic structure of the complex. At a simple level, the main interactions experienced by the TMI that consequently influence the EPR spectrum are (i) the electronic Zeeman effect and (ii) interaction between the electron and the nuclear spin. In the first case, the interaction is expressed via the g tensor which

Figure 1 EPR spectra arising from a ^{14}N ($I=1$) interaction showing (a) randomly and rigidly oriented in a frozen matrix; (b) antisotropic motion in a randomly oriented environment; (c) isotropic spectrum with no restriction on movement.

carries information on electronic structure; in the second case, the metal hyperfine interaction is expressed via the A tensor.

Although the information regarding the transition metal compound can be comprehensive, we shall confine ourselves here to a simple illustration of the power of EPR for investigating the symmetry of the metal centre in the solid state. The simplest case arises for TMI with one d electron. For a metal in a tetragonally distorted octahedral field experiencing compression along the 4-fold axis (D_{4h}), the five d orbitals have the splittings shown in **Figure 2** with the nondegenerate d_{yz} state lowest in energy. For a slight distortion, the low-lying 2-fold degenerate excited states (d_{xy} , d_{xz}) are close to the ground state, as depicted in **Figure 2a**. The small energy separation Δ_1 results in a short relaxation time with the result that the EPR signal can only be observed at low temperatures. Greater distortions lead to longer relaxation times, so that the EPR signals become observable at

increasingly higher temperatures with $g_{\perp} > g_{\parallel}$ as shown in **Figure 2a**. In the case of elongation along the 4-fold axis, the unpaired electron now occupies a doubly degenerate ground state (d_{xz} , d_{yz}) and no EPR signal is observed. However, if the ion experiences a trigonal distortion with a resulting point symmetry of D_{3d} as shown in **Figure 2b**, then the single electron occupies the d_{z^2} orbital so the order of the g -values changes or becomes 'inverted' (i.e. $g_{\parallel} > g_{\perp}$) as depicted in **Figure 2b**. This simple example illustrates the effects of the ground state of the TMI on the resulting EPR spectrum.

As shown above, the point symmetry at the metal can therefore be reflected in the g values, but the A values can also be influenced in a similar manner. Furthermore, depending on the point symmetry, the principal axes of g and A may or may not be coincident. The relationship between these tensors, the EPR spectral characteristics and the point symmetry of the metal are shown in **Table 3**. The importance of these relationships is that each type of EPR

Figure 2 Orbitals and corresponding EPR spectrum for an octahedral complex with (a) tetragonal and (b) trigonal distortion.

Table 3 Relationship between *g* and *A* tensor, EPR symmetry and the point symmetry of the paramagnets

EPR symmetry	<i>g</i> and <i>A</i> tensors	Coincidence of tensor axis	Molecular point symmetry
Isotropic	$g_{xx} = g_{yy} = g_{zz}$ $A_{xx} = A_{yy} = A_{zz}$	All coincident	O_h, T_d, O, T_h, T
Axial	$g_{xx} = g_{yy} \neq g_{zz}$ $A_{xx} = A_{yy} \neq A_{zz}$	All coincident	$D_{4h}, C_{4v}, D_4, D_{2d}, D_{6h}, C_{6v}, D_6, D_{3h}, D_{3d}, C_{3v}, D_3$
Rhombic	$g_{xx} \neq g_{yy} \neq g_{zz}$ $A_{xx} \neq A_{yy} \neq A_{zz}$	All coincident	D_{2h}, C_{2v}, D_2
Monoclinic	$g_{xx} \neq g_{yy} \neq g_{zz}$ $A_{xx} \neq A_{yy} \neq A_{zz}$	One axis of <i>g</i> and <i>A</i> coincident	C_{2h}, C_s, C_2
Triclinic	$g_{xx} \neq g_{yy} \neq g_{zz}$ $A_{xx} \neq A_{yy} \neq A_{zz}$	Complete non-coincidence	C_1, C_i
Axial non-collinear	$g_{xx} \neq g_{yy} \neq g_{zz}$ $A_{xx} = A_{yy} \neq A_{zz}$	Only g_{zz} and A_{zz} coincident	$C_3, S_6, C_4, S_4, C_{4h}, C_6, C_{3h}, C_{6h}$

behaviour is associated with a restricted number of point symmetries, which places constraints upon the geometrical structures of the paramagnet. For example, if the paramagnet is known to have, say, rhombic symmetry, then the associated geometry must belong to one of the point groups D_{2h} , C_{2v} or D_2 (Table 3). It would be incorrect to assign a structure that belongs to a more symmetric arrangement, e.g. D_{4h} which is strictly axial. Therefore, for a system with unknown structure, if the EPR symmetry can be determined (Table 3), we have invaluable structural information since the paramagnet can only belong to a restricted range of point symmetries. As an example, consider the EPR spectrum of $H_2[V(R,R\text{-HIDPA})_2]$ diluted in the corresponding zirconium compound (Figure 3b). At first glance the spectrum appears to have axial symmetry, since the features associated with the *x* and *y* directions are not split. Simulation of a spectrum based purely on axial symmetry is not entirely satisfactory (Figure 3a). The introduction of a small anisotropy in both g_{xx} , g_{yy} and A_{xx} , A_{yy} , however, produces an improved simulation (Figure 3c). Although the rhombicity is small, it is consistent with the known structure of the compound. From the crystallographic data, the highest possible point symmetry at the vanadium is C_2 . In more complex cases, other techniques such as variable-frequency CW-EPR, ENDOR and ESEEM are required to provide a more detailed description on the electronic structure of transition metal complexes. Nevertheless, one can start to appreciate the power of CW-EPR for studies of paramagnetic transition metal complexes.

Surface Chemistry and Catalysis

EPR has been widely applied to surface science and catalysis in order to examine a variety of surface paramagnetic species important in catalytic processes including adsorbed atoms, ions or molecules that may be intermediates in chemical reactions, intrinsic surface defects, transition metal ions supported on an oxide and spin labels interacting with a surface. Information regarding the important physicochemical characteristics of the surface can be gained through analysis of the EPR spectrum. Properties such as surface crystal field, surface

redox properties, surface group morphology, mobility of adsorbed species, coordination of surface metal ions and identification of the active site have been studied on a variety of surfaces.

In many cases, the surface itself is diamagnetic and investigations by EPR rely on indirect methods. A large amount of information regarding the state of a surface can be gained by adsorption of probe molecules (i.e. a molecule whose properties in the adsorbed state can be monitored and evaluated by EPR). These molecules may be divided roughly into two classes. The first is paramagnetic probes (or probes that become paramagnetic upon adsorption). The spectroscopic features of simple paramagnetic probes such as NO and O_2^- can provide detailed information on surface electrostatic fields. For example, the g values of the adsorbed superoxide anion (O_2^-) are known to depend not only on the nominal charge of the surface cation where adsorption occurs but also on the coordination environment of the cation itself, as shown in **Figure 4**. Paramagnetic probes such as VCl_4 or $MoCl_5$ retain their paramagnetism during reaction with surface hydroxyl groups, allowing one to study the distribution of the surface groups themselves. The other type are diamagnetic probes that remain diamagnetic upon adsorption. These probes allow one to investigate the properties of a paramagnetic adsorption site, such as the changes in the coordination sphere of a surface transition metal ion.

Metal oxides are frequently involved in catalysis, either directly or indirectly as supports. By studying the charge transfer reactions at the gas–solid or liquid–solid interface, the nature, number and strength of the acidic or basic catalyst can be investigated. The oxidizing properties of the oxide can be studied by formation of the radical cations of aromatic molecules such as anthracene and perylene, while the reducing properties of the surface can be monitored through the formation of the radical anions of molecules with large electron affinity such as tetracyanoethylene (TCNE) or nitroaromatic compounds. The EPR spectra of the corresponding radical cations and anions yield both qualitative and quantitative information on the redox nature of the surface and the subject has been reviewed.

Finally, a molecular approach to catalysis requires a deep understanding of the coordination processes occurring at the catalyst surface. The use of EPR to investigate the various types of coordination chemistry that occur on catalytic systems involving transition metal ions and oxide matrices has been reviewed. It has been shown that the reactivity and properties of the central transition metal ion in the heterogeneous system are heavily influenced by the coordinating ligands (much more than in the homogeneous counterparts) so that a variety of TMI complexes can be created and stabilized at the surface. Changes to the EPR spectroscopic features as a function of variation in the coordination sphere of a surface-

Figure 4 Simulated EPR spectra of the superoxide (O_2^-) anion adsorbed on differently charged cationic sites. The g_{zz} values of the radical have the form $g_{zz} = g_e + 2\lambda/\Delta$ where λ is the spin–orbit coupling constant for oxygen and Δ is the extent of the energy splitting between the two π^* orbitals, caused by the local electrostatic field of the cation. As the charge varies, Δ will vary and different g_{zz} values are observed (a–d). The anion is also sensitive enough to distinguish between cations with the same nominal charge which, because of different coordinative environments (e.g. 5-coordinated, 4c or 3c surface cations), exert slightly different electrostatic fields (e).

supported TMI can easily be followed. An example of this is shown in **Figure 5** for a Ni^+ supported catalyst. Changes in the spectroscopic features of the signal as a function of differing CO pressures illustrate the sensitivity of the technique to perturbations in the local environment. This coordination chemistry approach to EPR studies of the mechanism of catalytic reactions is illustrated in the dimerization of olefins and the oxidation of methanol on the surface of oxide catalysts.

Applications of Pulsed Techniques and High-Frequency EPR

The applications discussed above were performed using conventional CW (continuous wave) methods, predominantly at X-band (~ 9 GHz) frequency. However, EPR spectroscopy has experienced an extraordinarily rapid

Figure 5 X-band EPR spectra of Ni^+ complexes formed upon CO adsorption on reduced Ni/SiO_2 catalysts under a pressure of (a) 10 torr CO followed by evacuation at 340 K, (b) 10 torr, (c) 100 torr, (d) 400 torr. development in two noted areas, namely pulsed techniques and high-frequency EPR. Already both developments have proved to be invaluable tools in important areas of physics, chemistry and biology, and no article on the applications of EPR spectroscopy is complete without an explanation of the powerful attributes of these techniques.

The difference between high-frequency and low-frequency EPR is usually defined by the magnet system. Superconducting or Bitter magnets are employed for high-frequency EPR (such as those operating at 94 GHz), whereas traditional electromagnets are used for lower frequencies (e.g. Q-band (~ 35 GHz) to L-band (~ 1 GHz)). High-frequency EPR offers numerous advantages over the low-frequency spectrometers, including increased resolution of g factors (which is particularly important in complex or disordered systems where spectral lines are not resolved at lower fields) and increased absolute sensitivity (which is important in studies of small single crystals or any system where the number of spins is inherently low). High-frequency EPR also allows measurement of a number of integer-spin systems (such as

Ni(II) species) which often have very high zero-field splittings. These systems only start to become resolved at high frequency where the energy of the photon is above the zero-field energy. The number of applications is growing rapidly, but the most compelling areas of development are in complex disordered systems prevalent in structural biology, including new insights into the detailed mechanisms associated with photosynthesis and many metalloproteins. Because EPR is only sensitive to the sites with unpaired spins, it targets only the most important bonds that largely determine the chemical and physical properties of the metalloprotein. High-frequency EPR is also particularly appropriate for studying these complex enzymes since the active sites often involve metal ions or metal clusters with high zero-field splittings, which are EPR-silent at low frequency. Furthermore, most disordered systems are better studied at high frequencies because the improved spectral resolution allows the local structure to be inferred, especially in conjunction with other techniques such as ENDOR.

Exploitation of pulsed techniques in chemical research has been hampered in the past by expensive

instrumentation and the lack of sufficiently fast digital electronics. The situation has now undoubtedly changed and the various pulsed EPR methods have found increased or exclusive use in areas such as time-resolved EPR, as tools for studying molecular motion, in electron–nuclear double resonance spectroscopy and in EPR imaging. Fourier transform EPR has proved particularly useful for studying the various spin polarization mechanisms involved in free radical chemistry, while the very high time resolution involved in echo-detected EPR makes it an ideal technique for measuring rates of chemical reactions and determining relaxation times.

The underlying basis of pulsed EPR, like NMR, requires the generation of a spin echo by a short intense microwave pulse. However, in some cases the coupling between the electron spin and the nuclear spins can cause a modulation of the echo intensity. As this electron spin echo envelope modulation (ESEEM) can only occur if anisotropic interactions are present, it is only found in the solid state. Analysis of the ESEEM spectra allows determination of very small hyperfine couplings which are too small to be measured by CW-EPR, so that information on the number, identity and distance of weakly interacting nuclei may be obtained. A wide variety of applications of the nuclear modulation effect have been demonstrated, including determination of ligand structure in metalloproteins, magnetic properties of triplet states and location and coordination of surface complexes. In fact, the ESEEM method ranks with EXAFS as one of the most important tools for determining the structures of active centres in metalloproteins.

Conclusions

It is intended in this article to demonstrate the diversity of applications in which CW-EPR is traditionally used, while briefly describing some current uses of more advanced EPR techniques. However, with recent technological developments in FT-EPR, pulsed ENDOR, EPR imaging and high-frequency EPR, new and previously undreamed of prospects are likely to emerge. In many

cases the spectroscopic data of interest cannot be obtained by any other method. This fact alone will ensure EPR a place as an important spectroscopic technique well into the future.

Introduction

Chemical exchange, in NMR terms, means that a nucleus moves among a set of magnetic environments. The sample is macroscopically at equilibrium, but an individual nucleus exchanges among a number of sites, so the magnetic properties of the nucleus are modulated by the exchange. Chemical exchange effects were recognized early in the development of NMR: at about the same time (and in the same laboratory) as the scalar coupling. In *N,N'*-dimethyl formamide and many other molecules with *N,N'*-dimethyl groups (Figure 1), the two methyl groups have different chemical shifts if the molecule is rigid. At low temperature this is effectively the case, because of restricted rotation about the C–N bond. However, as the sample is warmed, the two signals broaden, coalesce, and eventually start to sharpen up to a single line at the average chemical shift, as shown in Figure 1.

This behaviour is usually interpreted in terms of an ‘NMR timescale’. For rotation about the C–N bond, which is slow on this timescale at low temperature, the two signals are distinct and relatively sharp. At higher temperature, the rotation is faster and all that one can detect is the average resonance frequency. The broad coalescence line shape is characteristic of the intermediate timescale, and is perhaps the most familiar and obvious manifestation of chemical exchange. This article concentrates on intermediate exchange, because a thorough understanding of this case clarifies most other aspects of chemical exchange.

Chemical exchange in all three regimes – slow, intermediate and fast – has an effect on the NMR spectrum.

3-Dimethylamino-7-methyl-1,2,4-benzotriazine

Figure 1 ^1H NMR spectra of the two *N*-methyl groups in 3-dimethylamino-7-methyl-1,2,4-benzotriazine, as a function of temperature.

Typical values of the parameters mean that processes with rates in the range of $1\text{--}10^4\text{ s}^{-1}$ can be studied most easily. In other words, this means activation energies for the reaction are in the range of approximately $40\text{--}80\text{ kJ mol}^{-1}$ ($10\text{--}20\text{ kcal mol}^{-1}$). This includes conformational changes in ring structures, restricted rotations about chemical bonds, ligand rearrangements in coordination complexes, and some intermolecular transfer processes. Molecules are dynamic entities, so the effects of chemical exchange are apparent in many NMR spectra.

The theory of chemical exchange is simple; uncoupled spin systems have often been couched in terms of the Bloch equations, and this is the approach used in most of the literature. However, it is simpler and easier to consider the time domain. This time-domain method allows us to treat all exchanging systems – slow, intermediate or fast, coupled or uncoupled – in a consistent and simple way. There is also a simple physical picture of the spectroscopic transition probability that helps in this interpretation of the theory.

The Bloch Equations Approach

The Bloch equations for the motion of the x and y magnetizations (usually called the u - and v -mode signals), in the presence of a weak radiofrequency field, B_1 , are given in the following equation.

$$\begin{aligned}\frac{du}{dt} + \frac{u}{T_2} - (\omega_0 - \omega_1)v &= 0 \\ \frac{dv}{dt} + \frac{v}{T_2} - (\omega_0 - \omega_1)u &= \gamma B_1 M_z\end{aligned}\quad [1]$$

In this equation, ω_1 is the frequency of the RF irradiation, ω_0 is the Larmor frequency of the spin, T_2 is the spin–spin relaxation time and M_z is the z magnetization of the spin system. The notation can be simplified by defining a complex magnetization, M

$$M = u + iv \quad [2]$$

With this definition, the Bloch equations can be written as

$$\frac{dM}{dt} + i(\omega_0 - \omega_1)M + \frac{1}{T_2}M = i\gamma B_1 M_z \quad [3]$$

In chemical exchange, the two exchanging sites, A and B will have different Larmor frequencies, ω_A and ω_B . The exchange will carry magnetization from A to B and vice versa. If we assume equal populations in the two sites, and the rate of exchange to be k , then we can set up

two coupled Bloch equations for the two sites, as

$$\begin{aligned}\frac{dM_A}{dt} + i(\omega_A - \omega_1)M_A + \frac{1}{T_2}M_A - kM_B + kM_A \\ = i\gamma B_1 M_{zA} \frac{dM_B}{dt} + i(\omega_B - \omega_1)M_B + \frac{1}{T_2}M_B - kM_A + kM_B \\ = i\gamma B_1 M_{zB}\end{aligned}\quad [4]$$

The observable NMR signal is the imaginary part of the sum of the two steady-state magnetizations, M_A and M_B . The steady state implies that the time derivatives are zero, and a little further calculation (and neglect of T_2 terms) gives the NMR spectrum of an exchanging system as

$$\begin{aligned}v &= \frac{1}{2} \gamma B_1 M_z \\ &\times \frac{k(\omega_A - \omega_B)^2}{(\omega_A - \omega_1)^2(\omega_B - \omega_1)^2 + 4k^2[\omega_1 - (\omega_A + \omega_B)/2]^2}\end{aligned}\quad [5]$$

This equation can be further extended to systems with unequal populations and more sites, using the same techniques.

Chemical Exchange in the Time Domain

If we create (by a pulse) the magnetization, M_A and M_B , at time zero, and then turn off the B_1 magnetic field, eqn [4] can be simplified as

$$\frac{d}{dt} \begin{pmatrix} M_A \\ M_B \end{pmatrix} = -L \begin{pmatrix} M_A \\ M_B \end{pmatrix} \quad [6]$$

$$L = \begin{pmatrix} i\delta + \frac{1}{T_2} + k & -k \\ -k & -i\delta + \frac{1}{T_2} + k \end{pmatrix} \quad [7]$$

In this equation, the matrix L is given by eqn [7], where we have made $\omega_1 = (\omega_A + \omega_B)/2$ and $\delta = (\omega_A - \omega_B)/2$:

$$\begin{pmatrix} M_A(t) \\ M_B(t) \end{pmatrix} = \exp(-Lt) \begin{pmatrix} M_A(0) \\ M_B(0) \end{pmatrix} \quad [8]$$

Equation [6] is a set of first-order differential equations, so its formal solution is given by eqn [8], in which $\exp()$ means the exponential of the matrix. In practice, we diagonalize the matrix L with a matrix of eigenvectors, U , as in eqn [9] to give a diagonal matrix, Λ , with the eigenvalues of L down the diagonal:

$$\Lambda = U^{-1}LU \quad [9]$$

Equation [8] becomes eqn [10]. The exponential of a diagonal matrix is again a diagonal matrix with exponentials of the diagonal elements, as in eqn [11].

$$\begin{pmatrix} M_A(t) \\ M_B(t) \end{pmatrix} = U \exp(-\Lambda t) U^{-1} \begin{pmatrix} M_A(0) \\ M_B(0) \end{pmatrix} \quad [10]$$

$$\begin{pmatrix} M_A(t) \\ M_B(t) \end{pmatrix} = U \begin{pmatrix} e^{-\lambda_1 t} & 0 \\ 0 & e^{-\lambda_2 t} \end{pmatrix} U^{-1} \begin{pmatrix} M_A(0) \\ M_B(0) \end{pmatrix} \quad [11]$$

As was mentioned earlier, the observed signal is the imaginary part of the sum of M_A and M_B , so eqn [11] predicts that the observed signal will be the sum of two exponentials, evolving at the frequencies λ_1 and λ_2 . This is the free induction decay (FID). In the limit of no exchange, the two frequencies are simply ω_A and ω_B , as we would expect. When k is non-zero, the mathematics becomes slightly more complicated.

If we ignore relaxation and exchange, then L is a Hermitian matrix with real eigenvalues and eigenvectors. However, when the exchange is important, the Hermitian character is lost and the eigenvalues and eigenvectors have both real and imaginary parts. The eigenvalues are given by the roots of the characteristic equation:

$$\begin{vmatrix} i\delta + \frac{1}{T_2} + k - \lambda & -k \\ -k & -i\delta + \frac{1}{T_2} + k - \lambda \end{vmatrix} = 0 \quad [12]$$

The eigenvalues of eqn [7] are given by the following equation:

$$\lambda = \left(\frac{1}{T_2} + k \right) \pm \sqrt{k^2 - \delta^2} \quad [13]$$

These eigenvalues are the (complex) frequencies of the lines in the spectrum, as in eqn [11]: the imaginary part gives the oscillation frequency and the real part gives the rate of decay. If $k < \delta$ (slow exchange) then there are two different imaginary frequencies, which become $\pm \delta$ in the limit of small k (see **Figure 2**). In fast exchange, when k exceeds the shift difference, δ , the quantity in the square root in [13] becomes positive, so the roots are pure real. This means that the spectrum is still two lines, but they are both at the average chemical shift and have different widths. The full expressions for these line shapes are given in the Appendix.

Because of the role of the eigenvectors in eqn [11], the factor (amplitude) multiplying the complex exponential is itself complex. The magnitude of the complex amplitude gives the intensity of the line and its phase gives the phase of the line (the mixture of absorption and dispersion). In slow exchange, the two lines have the same real

Figure 2 Decomposition of the coalescence line shape into individual lines. Top: experimental spectrum from **Figure 1**; middle: calculated line shape to match experimental spectrum; bottom: individual lines calculated as in the Appendix.

part, but the imaginary parts have opposite signs, so the phase distortion is opposite. The sum of these distorted line shapes gives the familiar coalescence spectrum, as in **Figure 2**. In fast exchange, the two lines are both in phase, but one line is negative. This negative line is very broad, and decreases in absolute intensity as the rate increases, leaving only the single, positive, in-phase line for fast exchange.

Therefore, the real and imaginary parts of the frequency and the real and imaginary parts of the amplitude provide the four parameters that define a line in an NMR spectrum: its intensity, its phase, its position and its width. This gives us a time-domain picture of the chemical exchange, which can easily be converted to a spectrum by using the Fourier transform.

Systems with Scalar Coupling

Scalar coupled systems are more complicated, but fundamentally no different from the uncoupled systems described in the time domain. If there is scalar coupling in the spectrum, the line shape becomes more complex. For instance, **Figure 3** shows the line shape of the diacetylpyridine ligand as part of a rhenium complex. The rhenium bonds to the pyridine nitrogen and to only one of the carbonyls, lifting the symmetry of protons 3 and 5. However, the rhenium can break this latter

Figure 3 Example of chemical exchange in a coupled spin system. The rhenium can bond to one or other of the carbonyl oxygen atoms so that the symmetry of the molecule is lifted. Exchange of the rhenium between carbonyl groups broadens the signals of protons 3 and 5 (at 8.46 ppm and 7.82 ppm), but leaves 4 (8.38 ppm) unaffected.

coordination and bond to the other carbonyl, which effectively interchanges protons 3 and 5 on the pyridine ring. During this exchange, they retain their coupling to the central proton 4, and the shift of 4 does not change. Therefore, proton 4 remains as a sharp triplet even when protons 3 and 5 are very broad.

In any strongly coupled spin system, each line in the spectrum is a mixture of transitions of various nuclei, which depends on the chemical shifts and coupling constants. When a chemical exchange happens, all the spectral parameters change with it. Therefore, a magnetization (or a coherence) that was associated with a single spectral line in one site may be spread among several lines in the other site. To deal with these complexities, we must use the density matrix.

One way of thinking of the density matrix is that it is a list of all the observables of a spin system. For example, the magnetizations of the two exchanging sites form part of the density matrix for that system. At equilibrium, the density matrix is just the z magnetization created by the static magnetic field. In a pulse Fourier transform NMR experiment, this z magnetization is flipped into the xy

plane and divided among the individual lines in the spectrum, which then precess around the z axis.

To calculate the spectrum of the system (or any other observable), we need to be able to follow the density matrix as a function of time. The equation of motion of the density matrix (ρ) is given in eqn [14], where H is the Hamiltonian of the spin system.

$$i\frac{b}{2\pi}\frac{\partial}{\partial t}\rho = [H, \rho] \quad [14]$$

Some manipulation allows us to reformulate eqn [14] as eqn [15]. Mathematically, this means using superoperators in Liouville space L , but the details need not concern us here. The important point is that the density matrix becomes a vector of all possible observables of the system – in this case we only deal with the xy magnetizations. Anything done to the system – pulses, free precession, relaxation, exchange, is represented by a matrix:

$$i\frac{b}{2\pi}\frac{\partial}{\partial t}\rho = L^{\text{so}}\rho \quad [15]$$

If we use frequency units ($b/2\pi = 1$), then the solution to eqn [15] is given in eqn [16], which is identical to eqn [8]:

$$\rho(t) = \exp(-iL^{\text{so}}t)\rho(0) \quad [16]$$

Relaxation or chemical exchange can be easily added in Liouville space, by including a Redfield matrix, R^{so} (so = superoperator), for relaxation, or a kinetic matrix, K^{so} , to describe exchange. Both relaxation and exchange are described very conveniently by superoperators. The complete equation of motion becomes eqn [17]. Note the similarity to the equations for two uncoupled sites, but now we derived them rigorously from the equations of motion of the density matrix:

$$\begin{aligned} \rho(t) &= \exp(-iL^{\text{so}} - R^{\text{so}} - K^{\text{so}}t)\rho(0) \\ &= U \exp(-\Lambda t)U^{-1}\rho(0) \end{aligned} \quad [17]$$

The details of what the density matrix is at time zero, what we observe in the receiver and how we construct the superoperators for a general spin system are all beyond the scope of this article. However, the basic idea remains: even the most complex exchange line shape is a sum of individual lines, with complex frequencies and complex intensities, as in eqn [17]. Each of those lines has a transition probability.

Physical Interpretation of the Transition Probability

The standard expression for the probability of a transition from an initial state, ψ , to a final state, ϕ , induced

by a perturbation I_x (the RF field along x), is given as

$$\text{Transition probability} \propto |\langle \phi | I_x | \psi \rangle|^2 \quad [18]$$

The matrix element in eqn [18] can be written in a rather more complicated way, as in eqn [19].

$$\begin{aligned} & \langle \phi | I_x | \psi \rangle \\ &= \text{trace} \left\{ \begin{pmatrix} \langle \phi | I_x | \phi \rangle & \langle \psi | I_x | \phi \rangle \\ \langle \phi | I_x | \psi \rangle & \langle \psi | I_x | \psi \rangle \end{pmatrix} \times \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \right\} \quad [19] \end{aligned}$$

The reason for rewriting the equation is that the right-hand side can be interpreted as the dot product of the operator I_x with the operator $|\phi\rangle\langle\psi|$. In the Liouville space all the operators are vectors. The dot product in Liouville space is defined as the trace of the product of the operators in the original spin space. One important point is that eqn [19] is independent of basis set. The matrix element in eqn [18] becomes a simple dot product of two Liouville space vectors as in eqn [20].

$$\langle \phi | I_x | \psi \rangle = \begin{pmatrix} \langle \phi | I_x | \phi \rangle \\ \langle \psi | I_x | \phi \rangle \\ \langle \phi | I_x | \psi \rangle \\ \langle \psi | I_x | \psi \rangle \end{pmatrix} \cdot \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix} \quad [20]$$

A dot product of two vectors gives the projection of one vector on to the other, so eqn [20] defines the projection of $|\phi\rangle\langle\psi|$ onto I_x . In other words, this is the projection of the transition onto the total xy magnetization. The standard transition probability is the square of this projection.

This leads to a physical interpretation of the transition probability. The spin system at equilibrium is represented by the total z magnetization, F_z . This is the sum of the z magnetizations of the sites, weighted by the equilibrium populations of each site. To distinguish the weighted sum, we give this spin operator a symbol different from I_z . A pulse flips this into the xy plane, so that immediately after the pulse, the spin system is represented by F_x . Now each transition receives a share of the total x magnetization. Its share is given by the projection of the transition (as an operator) onto the operator F_x . The transitions evolve independently as a function of time. However, we do not observe the transition directly, but rather the total xy magnetization. The detector is simply a coil of wire, and we measure the xy magnetization as a function of time to give us an FID. Fourier transforming the FID gives us a spectrum. Therefore, each transition contributes to the total signal according to its projection along I_x . The intensity of a transition is the product of how much coherence it received from F_x at the start and how visible it is to the receiver.

Note that the Liouville matrix, $iL + R + K$ may not be Hermitian, but it can still be diagonalized. Its eigenvalues and eigenvectors are not necessarily real, however, and the inverse of U may not be its complex-conjugate transpose. If complex numbers are allowed in it, eqn [17] is a general result. Since Λ is a diagonal matrix we can expand in terms of the individual eigenvalues, λ_j . U can be applied ('backwards') to I_x to obtain the following equation

$$\text{NMR signal} = \sum_j (UI_x)_j^* (U^{-1}F_x)_j \exp(-i\lambda_j t) \quad [21]$$

Each of the terms in the sum is a transition. The NMR signal is always a sum of decaying sine waves, whose frequency and decay rate are given by the imaginary and the real parts of λ_j . The intensity is governed by the coefficients in eqn [21] of this term. This coefficient is the product of two terms. The first, $(UI_x)_j$, tells us how much the coherence overlaps with the receiver. The second term, $(U^{-1}F_x)_j$ tells us how much the coherence received from the equilibrium z magnetization. The product of these terms is the generalization of the transition probability. If we do not have relaxation, the two terms are complex conjugates, and we recover the normal transition probability. However, the transition probability for a general system may have an imaginary part. If we cling to idea that each term in eqn [21] represents a transition, then an individual transition may be out of phase at $t=0$. Immediately after the excitation pulse, the total magnetization will lie on the y -axis, but the individual components may not. However, our true observable is still only the FID. Whether we want to decompose it into individual transitions of individual spins depends very much on the system we are studying.

Example of Exchange of Coupled Spins

Provided we can construct the matrices, the description of exchange is quite simple. Again, the details are beyond our scope, but an example of the Liouvillian (no exchange) for a coupled spin system is given in eqn [22] for an AB spin system, with coupling constant J . The eigenvalues of this matrix are the familiar line positions of an AB system:

$$\begin{pmatrix} i\omega_A & iJ/2 & 0 & -iJ/2 \\ iJ/2 & i\omega_A & -iJ/2 & 0 \\ 0 & -iJ/2 & i\omega_B & iJ/2 \\ -iJ/2 & 0 & iJ/2 & i\omega_B \end{pmatrix} \quad [22]$$

If there is an exchange between A and B given by a rate k , then we set up the two blocks, as we set up the two

exchanging spins in the Bloch equations. Note that we have made spin A in one block exchange with spin B in the other. The full Liouvillian, including exchange, is given in eqn [23], in which dots replace zeroes to emphasize the form of the matrix.

In this particular case, called mutual exchange, the spins simply permute themselves. This matrix can be simplified to half its original size, as in eqn [24], but

$$\begin{pmatrix} i\omega_A - k & iJ/2 & \cdot & -iJ/2 & k & \cdot & \cdot & \cdot \\ iJ/2 & i\omega_A - k & -iJ/2 & \cdot & \cdot & k & \cdot & \cdot \\ \cdot & -iJ/2 & i\omega_B - k & iJ/2 & \cdot & \cdot & k & \cdot \\ -iJ/2 & \cdot & iJ/2 & i\omega_B - k & \cdot & \cdot & \cdot & k \\ k & \cdot & \cdot & \cdot & i\omega_B - k & iJ/2 & \cdot & -iJ/2 \\ \cdot & k & \cdot & \cdot & iJ/2 & i\omega_B - k & -iJ/2 & \cdot \\ \cdot & \cdot & k & \cdot & \cdot & -iJ/2 & i\omega_A - k & iJ/2 \\ \cdot & \cdot & \cdot & k & -iJ/2 & \cdot & iJ/2 & i\omega_A - k \end{pmatrix} \quad [23]$$

for non-mutual exchange we must retain eqn [23].

$$\begin{pmatrix} i\omega_A - k & iJ/2 & k & -iJ/2 \\ iJ/2 & i\omega_A - k & -iJ/2 & k \\ k & -iJ/2 & i\omega_B - k & iJ/2 \\ -iJ/2 & k & iJ/2 & i\omega_B - k \end{pmatrix} \quad [24]$$

Except for its size, this is exactly the same form as in our previous cases. The spectrum can therefore be expressed as a sum of four lines, as in **Figure 4**.

Slow Chemical Exchange

The term ‘slow’ in this case means that the exchange rate is much smaller than the frequency differences in the spectrum, so the lines in the spectrum are not significantly broadened. However, the exchange rate is still comparable with the spin–lattice relaxation times in the system. In this case, we can measure the rates by doing a modified spin–lattice relaxation experiment, pioneered by Hoffman and Forsen.

In the absence of exchange (and let us ignore dipolar relaxation), each z magnetization will relax back to equilibrium at a rate governed by its own T_1 as given in the following equation:

$$\frac{d}{dt}[M(t) - M(\infty)] = -\frac{1}{T_1}[M(t) - M(\infty)] \quad [25]$$

If we have two sites, A and B, then we can write the analogous equation for two sites as

$$\begin{aligned} \frac{d}{dt} \begin{bmatrix} M^A(t) - M^A(\infty) \\ M^B(t) - M^B(\infty) \end{bmatrix} \\ = \begin{pmatrix} \frac{1}{T_1^A} & 0 \\ 0 & \frac{1}{T_1^B} \end{pmatrix} \begin{bmatrix} M^A(t) - M^A(\infty) \\ M^B(t) - M^B(\infty) \end{bmatrix} \end{aligned} \quad [26]$$

If the two sites exchange with rate k during the relaxation, then a spin can relax either through normal spin–lattice relaxation processes or by exchanging with the other site. Equation [26] becomes

$$\begin{aligned} \frac{d}{dt} \begin{bmatrix} M^A(t) - M^A(\infty) \\ M^B(t) - M^B(\infty) \end{bmatrix} \\ = \begin{pmatrix} \frac{1}{T_1^A} - k & k \\ k & \frac{1}{T_1^B} - k \end{pmatrix} \begin{bmatrix} M^A(t) - M^A(\infty) \\ M^B(t) - M^B(\infty) \end{bmatrix} \end{aligned} \quad [27]$$

This equation is very similar to eqns [6] and [7]. The basic situation is just as in intermediate exchange, except that now we are dealing with z magnetizations rather than xy magnetizations. The frequencies are zero and the matrix now has pure real eigenvalues, but the approach is the same. In the time domain a relaxation experiment follows the z magnetizations as a function of time. As before, the time dependence is obtained by diagonalizing the relaxation–exchange matrix and calculating the magnetizations for each time at which they are sampled.

There are two main applications of slow chemical exchange: one is to determine the qualitative mechanism and the other is to measure the rates of the processes as accurately as possible. For the first case, in which there is a spectrum in slow exchange, the following mechanism needs to be established which site is exchanging with which. For this purpose, the homonuclear

Figure 4 Calculated spectra for mutual exchange in an AB spin system, as a function of exchange rate. The heavy traces are the total line shape and the lighter lines show the individual components. The bottom spectrum shows the typical static AB spectrum, which broadens and coalesces at higher rates of exchange.

two-dimensional (2D) experiment EXSY (exchange spectroscopy) (the same pulse sequence as NOESY (2D nuclear Overhauser effect spectroscopy), but involving exchange) is by far the best technique to use. If there is no exchange, then the spectrum lies along the diagonal and there are no cross-peaks. Exchange between sites leads to a pair of symmetrical cross-peaks joining the diagonal peaks of the same site, so the mechanism is very obvious.

The EXSY pulse sequence starts with two $\pi/2$ pulses separated by the incrementable delay, t_1 . This modulates the z magnetizations, so that the relaxation that occurs during the mixing time which follows, t_m , is frequency labelled. Finally, the z magnetizations are sampled with a third $\pi/2$ pulse. Magnetization from a

different site that enters via exchange will have a different frequency label. A two-dimensional Fourier transform then produces the spectrum. However, care must be taken in choosing the mixing time if there are multiple exchange processes. If the mixing time is too long, there is a substantial probability that a spin may have exchanged twice in that time, leading to spurious cross-peaks.

For careful rate measurements, once the mechanism is established, it is our opinion that one-dimensional (1D) methods are superior to quantitative 2D ones. Apart from the fact that 1D spectra can be integrated more easily, we also have more control over the experiment. Modern spectrometers can create almost any type of selective excitation, so that the conditions can be controlled at the start of the relaxation. For two sites, a non-selective inversion that inverts both sites equally will mask most of the exchange effects and the relaxation will be dominated by T_1 . However, if one site is inverted selectively, then that site can regain equilibrium by either T_1 processes or by exchanging with the other site that was left at equilibrium. The inverted signal will relax at roughly the sum of the exchange and spin-lattice relaxation rate, while the signal that was unperturbed at the start of the experiment shows a characteristic transient, as in **Figure 5**. For multiple sites, a wide range of initial conditions is available. Standard non-linear least-squares methods allow us to fit these curves and derive values for the rates involved.

Fast Exchange

In fast exchange, the spectrum has coalesced, usually to a single line, so the information in the spectrum is not so rich. For two equally populated sites, for instance, we get a single Lorentzian line with a width proportional to δ^2/k . The line width (or better, T_2) can be measured via a CPMG (Carr–Purcell pulse sequence, Meiboom–Gill modification) experiment or a $T_{1\rho}$ measurement. However, if we do not know the frequency difference, δ , we cannot obtain the rate. If the exchange rate is not too fast ($<10^4$ roughly) modifications of the T_2 experiments can help. Both experiments have an inherent timescale: in CPMG, it is the timing of the refocussing pulse; in $T_{1\rho}$, it is the precession frequency about the spin-locking field. If the exchange is fast with respect to the experiment, we measure a T_2 appropriate to the coalesced spectrum. If, however, the exchange is slower than the experimental timescale (but still fast with respect to the frequency difference), the apparent T_2 reflects the individual sites. As we change the timescale of the experiment, the apparent T_2 changes, and so a value for the rate itself can be obtained.

Figure 5 Inversion–recovery curves for slow exchange between two sites. Lines A and B are the results from one experiment. They show the recovery after a non-selective inversion of both sites, showing that the two sites have slightly different T_1 values. C and D are obtained from a different experiment. Line C shows the recovery of a site that has been selectively inverted, and line D shows the behaviour of the line that was not perturbed in this experiment. The inverted line relaxes faster due to a combination of spin–lattice, relaxation and exchange, and the unperturbed line shows the characteristic transient.

Conclusions

All of the effects of chemical exchange can be calculated by following the appropriate magnetizations as a function of time. For slow exchange, this is the complex coupling of relaxation and exchange that leads to transient behaviour in modified spin–lattice relaxation experiments. For intermediate exchange, the rather complex line shapes can always be decomposed into a sum of individual transitions, even though the transitions are distorted in phase, intensity, position and width by the dynamics of the system. For two uncoupled sites, this can be calculated quite easily, but for larger coupled systems the construction of the matrices may get complicated. However, the resulting lines are always governed by a transition probability, provided we extend our definition to allow probabilities with both real and imaginary parts. Working in the time domain is already familiar from Fourier transform spectroscopy and it provides a complete and simple approach to chemical exchange.

Appendix

Eigenvalues and Eigenvectors for Two-Site Exchange

For two-site equally populated chemical exchange, the two magnetizations at time zero are equal, so that eqn [11] can be written as in eqn [28], where the eigenvalues

are complex numbers.

$$\begin{pmatrix} M_A(t) \\ M_B(t) \end{pmatrix} = U \begin{pmatrix} e^{\lambda_1 t} & 0 \\ 0 & e^{\lambda_2 t} \end{pmatrix} U^{-1} \begin{pmatrix} 1 \\ 1 \end{pmatrix} \quad [28]$$

Since non- c Hermitian matrices are involved, the matrix formed by the eigenvectors will not be unitary, and will have four independent complex elements. These are simply called a , b , c and d , so that U is given by:

$$U = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \quad [29]$$

Regardless of whether U is unitary, its inverse is given by eqn [30], where Δ is the determinant of eqn [29]:

$$U^{-1} = \frac{1}{\Delta} \begin{pmatrix} d & -b \\ -c & a \end{pmatrix} \quad [30]$$

Equation [28] then says that the signal is given by the following, regardless of slow or fast exchange:

$$\begin{aligned} \text{Signal} = & \frac{(a+c)(d-b)}{\Delta} \exp(\lambda_1 t) \\ & + \frac{(b+d)(-c+a)}{\Delta} \exp(\lambda_2 t) \end{aligned} \quad [31]$$

The values of the eigenvectors have two forms, depending on whether $\delta > k$ (slow exchange) or $\delta < k$ (after coalescence). In the first case, the eigenvalues are

given as

$$\text{Eigenvalues} = -\left(\frac{1}{T_2} + k\right) \pm i\sqrt{\delta^2 - k^2} \quad [32]$$

and a convenient matrix of eigenvectors is given by

$$\begin{pmatrix} k & i(\sqrt{\delta^2 - k^2} + \delta) \\ -i(\sqrt{\delta^2 - k^2} + \delta) & k \end{pmatrix} \quad [33]$$

After coalescence, when the rate is greater than the frequency difference, the two transitions are both at zero frequency (i.e. the average chemical shift) but have different widths and intensities. The eigenvalues are pure real, as

$$\text{Eigenvalues} = -\left(\frac{1}{T_2} + k\right) \pm \sqrt{k^2 - \delta^2} \quad [34]$$

and the eigenvectors are similar, but reflect the fact that $k^2 - \delta^2$ is now positive:

$$\begin{pmatrix} \sqrt{k^2 - \delta^2} - i\delta & -\sqrt{k^2 - \delta^2} - i\delta \\ k & k \end{pmatrix} \quad [35]$$

Introduction

In chemical ionization mass spectrometry (CIMS), ionization of the gaseous analyte occurs via gas-phase ion–molecule reactions rather than by direct electron impact (EI), photon impact or field ionization. EI ionization of a reagent gas (present in large excess) is usually followed by ion–molecule reactions involving the initially formed ions and the reagent gas neutrals to produce the chemical ionization (CI) reagent ion or reagent ion array. Collision of the reagent ion(s) with the analyte (usually present at $\sim 1\%$ of the reagent gas pressure) produces one or more ions characteristic of the analyte. These initial analyte ions may undergo fragmentation or, infrequently, react further with the reagent gas to produce a final array of ions representing the CI mass spectrum of the analyte as produced by the specific reagent gas.

To a considerable extent, the usefulness of CIMS arises from the fact that a wide variety of reagent gases and, hence, reagent ions can be used to ionize the analyte; often the reagent system can be tailored to the problem to be solved. Problems amenable to solution by CI approaches include (a) molecular mass determination, (b) structure elucidation and (c) identification and quantification. In many instances, CI provides information that is complementary rather than supplementary to that obtained by EI, and often both approaches are used. After a brief discussion of instrumentation, the major approaches, in both positive ion and negative ion CI, to the solution of the above problems are discussed. The focus is primarily on the use of medium-pressure mass spectrometry; CI at atmospheric pressure or at much lower pressures in ion trapping instruments are discussed elsewhere.

Instrumentation

Most commonly, CI studies have been performed at total ion source pressures of 0.1 to 1 torr using conventional

sector, quadrupole or time-of-flight mass spectrometers with ion sources only slightly modified from those used for EI ionization. The essential change is that the ion source is made more gas-tight by using smaller electron beam entrance and ion beam exit slits; the latter is accomplished by having either exchangeable source volumes or a moveable ion exit slit assembly to change from EI to CI. Manufacturers now supply instruments capable of both EI and CI and incorporating enhanced pumping to maintain adequately low pressures in the remainder of the instrument when the source is operated at elevated pressures. Provision is made for introduction of the reagent gas and for introduction of the analyte by a heated inlet system, by a solids probe, by a direct exposure probe or by interfacing a gas chromatograph to the ion source. Capillary gas chromatography–CI mass spectrometry is a particularly powerful and sensitive approach to identification and quantification of the components of complex mixtures.

Brønsted Acid Chemical Ionization

Gaseous Brønsted acids, BH^+ , react with the analyte M primarily by the proton transfer reaction

Other, usually minor, reactions that are possible include hydride ion abstraction (eqn [2]) and charge exchange (eqn [3])

The enthalpy change for eqn [1] is given by

$$\Delta H^\circ = PA(B) - PA(M) \quad [4]$$

where the proton affinity of X , $PA(X)$, is given by

If $PA(M) > PA(B)$, the reaction is exothermic and normally occurs at the ion–neutral collision rate determined by ion-induced dipole and ion–dipole interactions. Conversely, if the reaction is endothermic, the rate

decreases exponentially by the enthalpy of activation and the sensitivity of the ionization process decreases.

Most of the exothermicity of eqn [1] resides in MH^+ and is available as internal energy to promote fragmentation of MH^+ . To maximize the probability of MH^+ formation, which provides molecular mass information, one uses the least exothermic reaction possible. On the other hand, structural information is derived from the fragment ions observed in the CI mass spectrum and more exothermic protonation may be desirable to promote such fragmentation. The fragmentation of the even-electron MH^+ ions usually involves elimination of even-electron stable molecules to form an even-electron fragment ion. Thus if the molecule contains a functional group Y, the fragmentation of MH^+ frequently involves elimination of the stable molecule HY. For RYH^+ , the tendency to eliminate HY is roughly inversely related to the PA of HY, with the result that the ease of loss of Y as HY is approximately

although the stability of the resulting ion also plays a role in competing loss of different functional groups from a common MH^+ . Obviously, the more readily fragmentation occurs, the less likely it is that MH^+ ions, giving molecular mass information, will be observed, although with suitable choice of reagent ions, MH^+ ions are frequently formed when no $M^{+\bullet}$ ions are observed in the EI mass spectrum. In other cases, such as hydroxylic compounds, the use of a Brønsted base CI (see below) may prove useful in obtaining molecular mass information.

Table 1 lists Brønsted acid reagent systems which have seen significant use, along with the major reactant ions and the proton affinities of the conjugate bases. Most organic molecules have PAs in the range 760–1000 kJ mol⁻¹. Thus protonation by H_3^+ will be strongly exothermic, while protonation in *i*-butane or ammonia CI will only be mildly exothermic or even endothermic. CH_4 as a reagent gas is unique in that it forms two reactant species, CH_5^+ and $C_2H_5^+$, in almost equal

abundance; the polar reagent gases H_2O , CH_3OH and NH_3 produce solvated protons with the extent of solvation depending on the partial pressure of the reagent gas. The usefulness of Brønsted acid CI in establishing molecular masses is illustrated by the comparison of the EI, CH_4 CI and NH_3 CI mass spectra of ephedrine in **Figure 1**. No molecular ion is observed in the EI mass spectra. By contrast, both the CH_4 CI and NH_3 CI mass spectra show abundant MH^+ (m/z 166) ions, clearly establishing the molecular mass. In line with the relative PAs of **Table 1**, the less exothermic protonation in NH_3 CI leads to less extensive fragmentation of the MH^+ ion. As is often the case, CH_4 CI provides not only molecular mass information (MH^+) but also structurally informative fragment ions; the fragmentation of protonated ephedrine is rationalized in **Scheme 1** and is seen to involve the formation of even-electron fragment ions by the elimination of small, stable, even-electron neutral

Figure 1 EI, CH_4 CI, and NH_3 CI mass spectra of ephedrine (relative intensity as a function of m/z).

Table 1 Brønsted acid reagent systems

Reagent gas	Reactant ion (BH^+)	PA(B) (kJ mol ⁻¹)
H_2	H_3^+	423.4
N_2O-H_2	N_2OH^+	580.7
CH_4	CH_5^+	550.6
	$C_2H_5^+$	680.3
H_2O	$H^+(H_2O)_n^a$	696.0
CH_3OH	$H^+(CH_3OH)_n^a$	773.6
<i>i</i> -C ₄ H ₁₀	$C_4H_9^+$	819.6
NH_3	$H^+(NH_3)_n^a$	853.5

^aDegree of solvation depends on partial pressure of reagent gas; proton affinity given for monosolvated proton.

**Scheme 1**

molecules (the numbers in **Scheme 1** indicate the m/z of the ionic fragment). In this case the CH_4 CI mass spectrum provides more structural information than the EI mass spectrum.

The effect of protonation exothermicity on the extent of fragmentation is shown more dramatically by the Brønsted acid CI mass spectra of the tripeptide H-Val-Pro-Leu-OH shown in **Figure 2** and obtained using mass-selected reactant ions. With NH_4^+ as the reactant ion [$\text{PA}(\text{NH}_3) = 853.5 \text{ kJ mol}^{-1}$] only MH^+ is observed, while the more exothermic protonation by C_2H_5^+ [$\text{PA}(\text{C}_2\text{H}_4) = 680.3 \text{ kJ mol}^{-1}$] leads to significant fragmentation of MH^+ , and the very exothermic protonation by N_2OH^+ [$\text{PA}(\text{N}_2\text{O}) = 580.7 \text{ kJ mol}^{-1}$] leads to essentially complete fragmentation of MH^+ .

Ammonia has a very high PA, with the result that NH_4^+ (and solvated forms thereof) will efficiently protonate only those analytes with a PA greater than about 860 kJ mol^{-1} ; in effect, this means that only nitrogen-containing analytes (such as in **Figure 1** and **2**) are efficiently protonated. Analytes with lower PAs, which contain a lone pair of electrons, frequently give M^+NH_4^+ adducts.

Charge Exchange Chemical Ionization

In charge exchange CI, the reagent gas is chosen to produce an odd-electron species $\text{R}^{+\bullet}$ on EI ionization. This ion reacts with the analyte M by charge exchange to produce, initially, the odd-electron molecular ion (eqn [6]), which may undergo further fragmentation (eqn [7]).

Since the $\text{M}^{+\bullet}$ ion formed initially is the same as that formed initially in EI ionization, the fragmentation

Figure 2 Brønsted acid CI mass spectra of H-Val-Pro-Leu-OH using (a) NH_4^+ , (b) C_2H_5^+ and (c) N_2OH^+ as reagent ions. reactions observed will be similar to those observed in EI mass spectra. The essential difference is that, while the $\text{M}^{+\bullet}$ ions formed by electron ionization have a wide range of internal energies, the $\text{M}^{+\bullet}$ ions formed by charge exchange have an internal energy, $E(\text{M}^{+\bullet})$, given approximately by

$$E(\text{M}^{+\bullet}) = \text{RE}(\text{R}^{+\bullet}) - \text{IE}(\text{M}) \quad [8]$$

where $\text{RE}(\text{R}^{+\bullet})$, the recombination of $\text{R}^{+\bullet}$, is defined by

and $\text{IE}(\text{M})$ is the adiabatic ionization energy of M.

Reagent systems have been developed (**Table 2**) giving reactant ions with recombination energies over the range 9.3–16 eV. By comparison, most organic molecules

Table 2 Charge exchange reagent systems

Reagent gas	Reactant ion ($R^{+\bullet}$)	$RE(R^{+\bullet})(\text{eV})$
C_6H_6	$\text{C}_6\text{H}_6^{+\bullet}$	9.3
$\text{N}_2\text{-CS}_2$	$\text{CS}_2^{+\bullet}$	~ 10.0
$\text{CO}_2\text{-C}_6\text{F}_6$	$\text{C}_6\text{F}_6^{+\bullet}$	10.2
CO-COS	$\text{COS}^{+\bullet}$	11.2
Xe	$\text{Xe}^{+\bullet}$	12.1, 13.4
CO_2	$\text{CO}_2^{+\bullet}$	13.8
Kr	$\text{Kr}^{+\bullet}$	14.0, 14.7
N_2	$\text{N}_2^{+\bullet}$	15.3
Ar	$\text{Ar}^{+\bullet}$	15.8, 15.9

have ionization energies in the range 8–12 eV, so that, by suitable choice of the charge exchange reagent, a wide range of internal energies can be imparted to the molecular ion in eqn [6]. A potential use of charge exchange ionization is to enhance differences in the mass spectra of isomeric molecules compared to EI ionization; the use of charge exchange has the advantage, compared to low-energy EI, that the sensitivity of ionization is maintained. This use of charge exchange is illustrated in **Figure 3** which compares the $\text{C}_6\text{F}_6^{+\bullet}$ charge exchange mass spectra of *cis*- and *trans*-4-methylcyclohexanol with 70 eV mass spectra. The low-energy charge exchange spectra are much simpler; more importantly, the differences in the spectra of the two isomers are much enhanced following charge exchange ionization. A particularly useful application of charge exchange ionization is for the selective ionization of specific components of mixtures. The principle of the method is illustrated in **Figure 4** which shows the ionization energies of alkanes, cycloalkanes, alkylbenzenes and alkylnaphthalenes (components of petroleum products) plotted as a function of molecular mass. Also shown, as horizontal lines, are recombination energies of $c\text{-C}_6\text{H}_{12}^{+\bullet}$, $\text{C}_6\text{H}_5\text{Cl}^{+\bullet}$ and $(\text{CH}_3)_3\text{C}_6\text{H}_3^{+\bullet}$. These species should ionize only those hydrocarbons with ionization below the appropriate line. Clearly, $\text{C}_6\text{H}_5\text{Cl}^{+\bullet}$ will ionize only the benzene and naphthalene components, while $(\text{CH}_3)_3\text{C}_6\text{H}_3^{+\bullet}$ will be even more selective for the naphthalenes and higher molecular mass benzenes.

Brønsted Base Chemical Ionization

Gaseous Brønsted bases, B^- , usually react with organic analytes M by proton abstraction to produce $[\text{M} - \text{H}]^-$ as the initial product.

Equation [10] is normally rapid provided it is exothermic, i.e. provided $\Delta H_{\text{acid}}^\circ(\text{BH}) > \Delta H_{\text{acid}}^\circ(\text{M})$ or,

Figure 3 EI and $\text{C}_6\text{F}_6^{+\bullet}$ charge exchange (CE) mass spectra of *cis*- and *trans*-4-methylcyclohexanol. alternatively, provided $\text{PA}(\text{B}^-) > \text{PA}([\text{M}-\text{H}]^-)$, where

$$\text{BH}_{(\text{g})} \rightarrow \text{B}_{(\text{g})}^- + \text{H}_{(\text{g})}^+ \quad [11]$$

$$\Delta H^\circ = \Delta H_{\text{acid}}^\circ(\text{BH}) = \text{PA}(\text{B}^-)$$

In general, little fragmentation of $[\text{M}-\text{H}]^-$ is observed, with the result that Brønsted base CI often provides molecular mass information through formation of the $[\text{M}-\text{H}]^-$ ion that is 1 amu lower than the molecular mass.

Table 3 lists possible Brønsted base reagents along with the $\Delta H_{\text{acid}}^\circ$ of the conjugate acid BH. For comparison, phenols have gas-phase acidities in the range of 1370–1465 kJ mol⁻¹, carboxylic acids have acidities in the range of 1350–1422 kJ mol⁻¹, alkynes in the range of 1520–1580 kJ mol⁻¹ and alkylbenzenes about 1590 kJ mol⁻¹. Also listed in the table are the electron affinities of the neutral species B; these are relevant to the tendency of B⁻ to react by electron transfer to form M^{-•}. These electron affinities are quite high with the exception of O₂^{-•} which is the only reactant likely to react by electron transfer to M.

Of the bases listed OH⁻ has seen by far the greatest use. It can be prepared by electron bombardment of a CH₄–N₂O (~90:10) mixture (at usual CI source pressures) through the reaction sequence

where the CH₄ also serves to thermalize the electrons. Alternatively, the addition of CH₃ONO to the methane bath gas leads to formation of CH₃O⁻. The Cl⁻ and Br⁻ ions can be prepared by dissociative electron capture by halogen-containing compounds such as CH₂Cl₂ or CH₂Br₂. The F⁻ ion is usually prepared by dissociative electron capture by NF₃. The OH⁻ ion is a strong base and will abstract a proton from most organic analytes to form $[\text{M}-\text{H}]^-$. Thus, OH⁻ CI can be usefully employed to obtain molecular mass information. For example, the OH⁻ CI mass spectra of ephedrine shows $[\text{M}-\text{H}]^-$ (*m/z* 164) as the dominant ion, and OH⁻ CI could be used as

Table 3 Brønsted base reagents

B ⁻	$\Delta H_{\text{acid}}^\circ(\text{BH})$ (kJ mol ⁻¹)	EA(B) (kJ mol ⁻¹)
NH ₂ ⁻	1690	75.3
OH ⁻	1636	176.6
O ^{-•}	1598	141.0
CH ₃ O ⁻	1594	151.5
F ⁻	1552	328.0
O ₂ ^{-•}	1477	42.3
Cl ⁻	1393	348.9
Br ⁻	1356	324.7

readily as CH₄ CI or NH₃ CI (Figure 1) to establish the molecular mass. More importantly, Brønsted base CI can often be used to provide molecular mass information in cases where Brønsted acid CI fails. This is illustrated in Figure 5 which compares the CH₄ CI and OH⁻ CI mass spectra of 2,3-cyclopropyl-1,4-undecanediol. While the CH₄ CI mass spectrum is quite uninformative (as is the EI mass spectrum), the OH⁻ CI mass spectrum shows an abundant $[\text{M}-\text{H}]^-$ (*m/z* 199) ion, as well as fragmentation by sequential loss of two water molecules from $[\text{M}-\text{H}]^-$. The hydroxyl ion can react with some RX molecules by an S_N2 reaction to give X⁻ and does react with esters, R' COOR, in part, by addition/elimination to give R'COO⁻ + ROH. The reactions of CH₃O⁻ have not been extensively studied; since it has a similar PA to that of OH⁻ one would expect the reactions to be similar. The F⁻ ion is a somewhat weaker base than OH⁻ or CH₃O⁻ and thus is somewhat more selective in its proton abstraction reactions. Cl⁻ is quite a weak base and will abstract only very acidic protons; in other cases $[\text{M} + \text{Cl}]^-$ adducts have been observed, which has proven useful in providing molecular mass information.

The O^{-•} ion, which can be produced by electron bombardment of a N₂–N₂O (~9:1) mixture, is unique in that it is both a strong Brønsted base and a radical.

Figure 5 CH₄ CI and OH⁻ CI mass spectra of 2,3-cyclopropyl-1,4-undecanediol (relative intensity as a function of *m/z*).

As a result, it reacts with many organic analytes not only by proton abstraction but also by H-atom abstraction, H_2^+ -abstraction and H-atom and alkyl group displacement. This variety of reactions is illustrated in **Figure 6** for C_5 ketones. The $[\text{M}-\text{H}_2]^-$ in ketones results to a significant extent by H_2^+ -abstraction from one α -carbon; the resultant ion undergoes further fragmentation by loss of the opposite alkyl group (see m/z 41, **Figure 6**, for example). Alkyl group displacement results in formation of carboxylate ions for ketones. Clearly O^- CI provides a greater possibility of isomer distinction than OH^- CI which produces only $[\text{M}-\text{H}]^-$. However, O^- CI usually has a considerably lower sensitivity than OH^- CI or Brønsted acid CI.

Electron Capture Chemical Ionization

In electron capture CI, ionization of the analyte M occurs by electron capture (eqn [14]) or by dissociative

electron capture (eqn [15]).

Both reactions are resonance processes that require electrons of near-thermal energy to occur efficiently. Typically, a high-pressure (0.1–1.0 torr) buffer gas is used to ‘thermalize’ the electrons (emitted from a heated filament) by inelastic scattering and positive ion ionization processes. Ideally, the buffer gas should not form stable anions, and buffer gases that have been used include He, H_2 , N_2 , CH_4 , NH_3 , CO_2 and $i\text{-C}_4\text{H}_{10}$. Polyatomic gases such as CH_4 , NH_3 , $i\text{-C}_4\text{H}_{10}$ or CO_2 have proven to be most efficient in promoting electron capture. The first three have seen the most use, in part because they are often used in Brønsted acid CI and are readily available.

The major attraction of electron capture chemical ionization (ECCI) is the prospect of enhanced sensitivity compared to other forms of CI or electron ionization. Whereas the maximum rate constants for the ion-molecule reactions involved in Brønsted acid or Brønsted base CI are in the range $(2\text{--}4) \times 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, electron capture rate constants can be as high as $10^{-7} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ because of the high mobility of the electron. Since the sensitivity of the ionization process depends, in part, on the rates of the ionization processes, in favourable circumstances ECCI can be up to 100 times more sensitive than other forms of ionization; this increase can be important when detection and quantification at trace levels is desired. At the same time the rate constants for electron capture are very compound-sensitive and can be very low, with the result that ECCI does show variable and, sometimes, very low sensitivity. It appears that only analytes with appreciable electron affinities (perhaps 0.5 eV) provide reasonable sensitivity in ECCI. The presence of halogen or nitro groups (particularly when attached to π -bonded systems), a conjugated carbonyl system or highly conjugated carbon systems lead to reasonably high electron affinities. Thus, as examples, dinitrophenols, dinitroanilines and polychlorinated aromatic compounds show good sensitivity in ECCI.

Analytes that are not suitable candidates for electron capture can often be made so by suitable derivatization. Perfluoracyl, pentafluorobenzyl, pentafluorobenzoyl and nitrobenzyl derivatives are often used not only to increase the electron capture rate constants but also to enhance chromatographic properties. However, in contrast to electron capture gas chromatography, it is not sufficient that electron capture be facile; in addition, ions characteristic of the analyte must be formed since ions characteristic only of the derivatizing agent leave the

Figure 6 O^- CI mass spectra of C_5 ketones (M_r 86). Data from Marshall A, Tkaczyk M, and Harrison AG (1991) O^- chemical ionization of carbonyl compounds. *Journal of the American Society of Mass Spectrometry* 2: 292–298.

^bRelative molar response.

identity of the analyte in question. This is illustrated by the data in **Table 4** for derivatization of phenols, where it can be seen that the perfluoroacyl derivatives yield ions characteristic only of the derivatizing agent, whereas the pentafluorobenzyl and pentafluorobenzoyl derivatives yield ions characteristic of the analyte. Also included in the table are the relative sensitivities (relative molar response) for the three derivatives which give ions identifying the analyte; clearly, the pentafluorobenzyl or pentafluorobenzoyl derivatives are to be preferred in this case.

In addition to variable sensitivity, two further problems that can be encountered in ECCI are non-reproducibility of the spectra and the observation of artifact peaks, i.e. ions that are not explainable simply on the basis of electron capture by the analyte. ECCI mass spectra tend to depend rather strongly on experimental conditions such as buffer gas identity and pressure, source temperature, purity of the buffer gas, amount of analyte introduced, instrument used and instrument focusing conditions. The variability of the spectra obtained is illustrated by the example in **Figure 7**. At 100 °C source temperature with CH₄ buffer gas, nordiazepam shows M^{-•} (*m/z* 170) as the only significant ion, while at 150 °C source temperature Cl⁻ is the dominant ion, and with 1 part in 2000 of oxygen in the methane, predominant formation of [M - H]⁻ (*m/z* 169) is observed. This amount of oxygen could easily be in the system if there is a small air leak. The occurrence of artifact peaks is illustrated in **Figure 8** which shows the ECCI spectra of tetracyanoquinodimethane with CH₄ and CO₂ as buffer gases. The major peaks in the spectrum with CH₄ buffer gas represent artifact peaks arising from reaction of the analyte with free radicals produced on electron bombardment of methane; these altered species are subsequently ionized by electron capture. By contrast, the spectrum with CO₂ buffer gas shows only M^{-•}. CO₂ clearly is preferred in this case

Figure 7 Electron capture CI mass spectra of nordiazepam under different conditions (relative intensity as a function of *m/z*). Data from Garland WA and Miwa BJ (1983) *Biomedical and Environmental Mass Spectrometry* 10: 126–129.

although when oxidation of the analyte occurs (such as formation of fluorenone from fluorene) the use of CO₂ as a buffer gas leads to substantial artifact peaks. It appears that the most prevalent pathway to these artifacts involves a surface-catalysed reaction of the analyte with some component of the reagent gas plasma, which produces one or more species with a higher cross section for electron capture than the original analyte. Alteration of the analyte presumably occurs when other ionization methods are used; the difference is that in other modes of CI all species are ionized with similar efficiencies, while in ECCI the altered species may be preferentially ionized.

Despite these difficulties with ECCI it is often the method of choice when identification and quantification at very low concentrations and/or involving complex mixtures are necessary. In such work it is necessary to

control the experimental parameters carefully since they can affect both spectra and sensitivity.

This article is reproduced from the previous edition, volume 1, pp 216–222, © 1999, Elsevier Ltd.

Introduction

This article covers applications of UV and visible electronic spectroscopy to studies of chemical reactivity. This encompasses both studies of reaction kinetics and of equilibria and chemical exchange phenomena. Chemical reactions can occur in different phases. Many of the reactions occur in the gas phase and the reactions which take place in this phase will be covered in the section on reaction kinetics.

In solution, the molar volume occupied by the molecules will be less than that in the gas phase; thus the molecules will come close together and the freedom for translational motion is restricted. There is another important difference between the solution and the gas phase, which is the great proximity between the solvent molecules and the solute molecules. The solvent can act as a heat sink and energy can pass between the solvent and solute, this affects the vibrational modes and may enable the reactants to overcome activation barriers. Solvent polarity will affect reactions in solutions containing ions. Polar solvents lower the energy required for the formation of ions. In solution many processes and reactions will take place such as diffusion-controlled reactions, reactions of hydrogen and hydroxyl ions, the formation of solvated molecules and electron transfer reactions. The rate coefficients depend on many factors such as the solvent and the formation of a solvent cage, the pressure and the ionic strength of the solution.

Many reactions take place on solid surfaces, and may be catalysed by the surface. Surface catalysis is very important in industry, and makes important contributions to some atmospheric reactions. Molecules will be adsorbed on solid surfaces through physisorption in which the attractive force between the reactant molecules and the surface is of the van der Waals type. Enthalpy of adsorption, ΔH_{ad} , of physisorption is relatively small, about -40 kJ mol^{-1} . With chemical sorption the value for the enthalpy of adsorption is large because a strong bond is formed between the chemical molecule and the surface. Catalytic reactions can be classified as homogeneous catalysis or heterogeneous catalysis.

UV-Visible Spectroscopy for Kinetics Studies

The Problem of Variable Response Factors

UV-visible spectroscopy has proved useful in biochemical analysis, environmental studies, in forensic science, drug

kinetics, food quality, identification and quantification of chemical and biological substances but is limited as a tool for the investigation of molecular structure compared with infrared and nuclear magnetic resonance. However, it is useful for the study of reaction kinetics and equilibrium.

There is a problem facing the use of a UV-visible spectrum for the calculation of the concentration of different species if two species absorb at the same region, and in this case there is a need to change the reagents to obtain different colours for different species. Also, it is important to carry out a close inspection for the two bands which have the same wavelength. An example of such a system is the absorption of potassium permanganate along with the absorption of a soluble azo dye, which appears as if it is absorbing at the same region, this being near 530 nm. A close inspection and calculations show that λ_{max} of KMnO_4 and the dye are 533 and 542 nm, respectively, while the extinction coefficients for KMnO_4 and the dye are 1.01 and $1.88 \times 10^{14} \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$, respectively.

Theory of UV Spectroscopy

In UV-visible spectroscopy it is the study of electronic energy that is of interest. This energy can be calculated from the observed bands in the UV-visible region of the spectrum (195–750 nm). The observed bands in this region are due to the excitation of the electrons by light of a certain wavelength, from the ground state to the excited state. This excitation of the energy of electrons between energy states is in accord with the Franck–Condon principle which states that an electronic transition in a molecule takes place so rapidly compared with the vibrational motion of the nuclei that the internuclear distance can be regarded as fixed during the transition.

The types of electronic transitions are given in Table 1. In organometallic compounds a very intense colour can arise due to the $d \rightarrow d$, $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions. This is true especially in transition metals connected to an organic molecule. Several factors, such as substitution (electronic and steric effect), solvent, temperature, and pH, will affect electronic transitions and band intensity and shape. In the following paragraphs a brief discussion is given.

Table 1 UV-visible absorption of some chromophores

Chromophore	Compound	Electronic transition	$\lambda_{\max}$ (nm)	ϵ^a ($\text{m}^2 \text{mol}^{-1}$)
C_6H_6	Benzene	$\pi \rightarrow \pi^*$	200, 255	800
$\text{C}=\text{C}$	Ethylene	$\pi \rightarrow \pi^*$	180	1300
$\text{C}=\text{O}$	Acetone	$\pi \rightarrow \pi^*$	185	95
		$n \rightarrow \pi^*$	277	2
$\text{N}=\text{N}$	Azomethane	$n \rightarrow \pi^*$	347	1
$\text{N}=\text{O}$	Nitrosobutane	$n \rightarrow \pi^*$	665	2

^aMolar absorptivity.

Sample Preparation

To obtain useful and accurate information from the UV-visible spectrum it is important to fix appropriate conditions for recording the spectrum. The studied material must be stable and not undergo decomposition by itself under the experimental conditions, which include concentration, solvent and temperature. The solute must dissolve completely in the solvent. It must not be colloidal, because this will give an error in the calculation of the different species present in solution. Also, the solution must not undergo hydrolysis or decomposition in this solvent; otherwise a new species will form which may not be soluble in the solvent.

Cells for the UV region below 330 nm are made of fused silica. In the case of the visible region glass cells may be used. Cells for special measurements can be used and they are classified as sampling cells, flow cells and rectangular cells.

In all measurements it is important to work with concentrations which are within the Beer–Lambert law. There is a need to carry out calibration so that by preparing different concentrations of the sample in the solvent and plotting the concentration against the recorded absorbance a straight line, results. It is necessary to use a concentration of the sample within this calibrated curve. The usual concentration, which is used in recording a UV-visible spectrum, is 10^{-3} – 10^{-5} M. The solute must not change its concentration due to decomposition or precipitation.

Solvent Effects

It is very important to choose the appropriate solvent. The best solvent is that which is able to solubilize the solute completely, which is inert and will not interact with the solute and thus cause a perturbation of its electronic structure, and which will not absorb in the region where the sample will absorb. **Table 2** gives the cutoff wavelength for a selective range of solvents.

Sometimes it is important to use a solvent with a high solubilizing ability like water, ethanol, etc. Solvents must be of high purity because the presence of impurities

Table 2 $\lambda_{\max}$ for different solvents

Solvent	$\lambda_{\max}$ (nm)
Water	165
Acetonitrile (spectroscopic grade)	190
Hexane	199
Heptane	200
Isocane	202
Diethyl ether	205
Ethanol	207
Propan-2-ol	209
Methanol	210
Cyclohexane	212
Acetonitrile (chemical grade)	213
Dioxan	216
Dichloromethane	233
Tetrahydrofuran	238
Trichloromethane	247
Tetrachloromethane	257
Dimethyl sulfoxide	270
Dimethylformamide	271
Benzene	280
Pyridine	306
Propanone	331

will affect the spectrum either through their own absorptions or by interacting with the solute. It is important to take into consideration the solvent effect on the solute. So if a solute dissolved in an inert solvent such as cyclohexane is taken as the reference absorption, then some solvents will cause the absorption of the solute to shift more to the red region and this shift is denoted as bathochromic or red-shift. Other solvents may cause the band to shift to the blue region and this is called blue-shift or hypsochromic. This phenomenon is important in UV-visible spectroscopy because it is possible to study the solute–solvent interactions and hydrogen bond strength. Some solute molecules can be used as a probe for measuring the solvent properties.

Light Absorption and Colour

Colour change is very important for the determination of different species present in the media whether they are the reacting species or the species formed during the reaction. From the spectra it is easy to calculate the concentration of all species and therefore to study the kinetics of the reaction.

Solution Conditions and Analysis

To obtain accurate data and concentrations for the different species present in solutions at specific times, it is important to obtain correct conditions for monitoring the species by the change of the absorbance of those species. It is important to determine the following conditions and their variation.

Temperature and its variation

It is possible to change the temperature and this will lead to a change of absorbance; thus, it is possible to calculate the activation energy of the reaction.

pH

This is very important for aqueous solutions. The pH can have a large effect on the UV-visible spectrum, rates of complexation or change in reaction kinetics. pH can have a pronounced effect on shifting the equilibrium in enol-keto tautomerism. A good example is the effect of pH on the equilibrium in the system dichromate/chromate.

Ionic strength

The ionic strength of the solution is important for some reactions, especially for solutions which contain ions other than the neutral reactant molecules; interaction will occur between ions other than the reactants and this will affect the rate constant.

Effect of pressure

For the majority of chemical reactions it is difficult to study the pressure effect. The reaction rate is insensitive to changes in pressure and a large pressure must be applied before any important change is observed. Sometimes it is necessary to study the effect of pressure because it provides a useful insight into the mechanism of the reaction.

Solvent polarity

In general, one should use solvents with low polarity so there will be no interference in the formation and decomposition of different species. On occasions, however, it is necessary to use solvents with high polarity to increase the solubility of the solutes or to affect the activation energy of a certain reaction.

Other factors that are important are the order of addition of different reagents, mixing and stirring to obtain solution homogeneity and choice of the proper wavelength which will be used to monitor the change of concentration during the reaction.

Specialized Techniques**Stopped flow method**

This method can be applied for the study of gases and liquids. The usual detection techniques are absorption spectrometry. High flow rates are required to promote mixing for fast reactions.

Flash photolysis and pulse radiolysis

In the flash photolysis technique a reactant is irradiated with an intense flash of visible or ultraviolet light. The intensity must be sufficient to produce a measurable

change in chemical composition, but of short duration compared with that of the ensuing reactions, which are to be studied.

Multidimensional spectroscopy and derivative spectroscopy

When bands of reactants and reaction products overlap in the fundamental UV-visible absorption spectra the reaction kinetics cannot be followed by the classic UV method. In many cases, second derivative UV-visible spectrophotometry (D-2) provides an alternative method to solve the problem. Even-order derivatives are suitable to follow kinetics because the maxima in the UV-visible derivative spectrum can be associated with the maxima and minima of the original spectrum; a low-noise online spectra is obtained which can be computed up to the 6th order derivative and even up to the 10th order with some spectroscopic software, although the higher-orders usually have limited value. On the other hand, the first derivative does not provide the above association; and other higher odd-order derivatives are less precise, though in practice it has proved valuable to work with spectra of the 3rd and 5th order.

Applications to Chemical Reactions

Many applications of UV-visible spectroscopy to the study of chemical reactions have been published and some illustrative examples which have been reported in the literature will be covered.

Complex Formation

The kinetics of transformation of complexes in organic media can be studied. Such studies will indicate whether the complexes will form in a one-step reaction mechanism or a multistep reaction mechanism. It is possible to determine the rate constants and the stability constant of the complex. UV-visible spectroscopy can be used to study the protonation of certain complexes and it is possible to obtain information on the position of protonation.

Reduction of complexes can be studied by UV-visible spectroscopy. Reduction of $\text{trans-[Pt(CN)}_4\text{X}_2\text{]}^{2-}$ ($\text{X} = \text{Cl}$ or Br) [as model compounds for antitumour-active platinum(IV) pro-drugs] to $[\text{Pt(CN)}_4]^{2-}$ by L-methionine, MeSR, has been studied at 25°C in the range $0 < \text{pH} < 12$ ($\text{X} = \text{Cl}$) and $0 < \text{pH} < 6$ ($\text{X} = \text{Br}$) by the use of stopped-flow spectrophotometry. It was concluded that methionine-containing biomolecules may compete with thiol compounds for reduction of platinum pro-drugs under acidic conditions, and also in neutral solutions with low concentrations of thiol-containing biomolecules.

The formation kinetics and the thermodynamic stability of iron(III) complexes with a tetradentate ligand,

N(α)-salicyl- L-alaninehydroxamic acid (H-2slalh), have been investigated by the use of UV-visible and stopped-flow spectrophotometric methods. By comparing the pH-dependent absorbance change, the mechanism of the complex formation was explained.

Photochemical Reactions

Photochemical behaviour of full-aromatic β -carboline, nor-harmane, harmane and harmine in chloroform medium and the corresponding UV absorption and fluorescence emission spectra have been discussed. Irreversible electron transfer from the singlet excited β -carboline molecule to the chloroform molecule in the transient excited charge transfer complex has been proposed as the primary photochemical process initiating the mechanism of secondary reactions in this system.

In deoxygenated water, methanol, and ethanol, 4-hydroxybenzonitrile (4-HBN) is photoisomerized into 4-hydroxybenzoinitrile (4-HBIN), which is then hydrolysed into 4-hydroxyformanilide in acidic medium. The triplet-triplet absorption of 4-HBN ($\lambda_{\text{max}} = 300 \text{ nm}$) is detected by transient absorption spectroscopy. The triplet is converted into long-lived transients absorbing in the far-UV. The analysis of the kinetics of 4-HBIN formation as a function of irradiating photon flux shows that the photoisomerization of 4-HBN is a two-stage photoprocess. According to triplet-quenching studies, the first stage proceeds via the 4-HBN triplet to yield an intermediate capable of absorbing a second UV photon, which then gives 4-HBIN in the second stage. Mechanistic considerations indicate that this intermediate is likely to be an arizine.

Tautomerism and Isomerization

Tautomerism is an important phenomenon and an example of this process is the equilibrium in Schiff bases. These bases can exist as an equilibrium between two species, keto $\rightleftharpoons$ enol [Scheme 1]. This process is affected by a number of factors such as solvent polarity, temperature and pH. The kinetics of tautomerism can be studied by UV-visible spectroscopy, and a few examples are shown here.

Scheme 1

The tautomerism between a hydroxy Schiff base and the corresponding ring-closed oxazolidine was kinetically studied in chloroform. This method indicated that this reaction is pseudo-first-order. UV examination was used to deduce the molecular species in various pH buffers. In an acid solution (e.g. pH 3.0) the Schiff base existed as the protonated Schiff base at the imine nitrogen atom, and in the alkaline region (e.g. pH 9.0) as the oxazolidine form.

The keto-enol equilibrium constants of acetylacetone, ethyl acetoacetate and ethyl benzoylacetate in water at 25 °C were determined by studying the influence of surfactants on their UV-visible spectra. These measured equilibrium constants were used to obtain the reactivity of the ketones towards several nitrosating agents.

Atmospheric, Environmental Reactions, Gas Phase and Free Radical Kinetics

The UV absorption cross-sections of peroxyacetyl nitrate (PAN), $\text{CH}_3\text{C}(\text{O})\text{O}_2\text{NO}_2$, have been measured as a function of temperature (298, 273 and 250 K) between 195 and 345 nm. Photolysis becomes the most important atmospheric loss process for PAN, and the OH reaction is found to unimportant throughout the troposphere.

The atmospheric chemistry of benzene oxide/oxepin, a possible intermediate in the atmospheric oxidation of aromatic hydrocarbons, has been investigated by visible and UV photolysis. The results indicated that the major atmospheric sinks of benzene oxide/oxepin are the reaction with OH radicals and photolysis and under smog chamber conditions, with high NO_2 concentrations, and also reaction with NO_3 .

A flash photolysis-resonance fluorescence technique was used to study the rate constant for the reaction of OH radicals with dimethyl carbonate over the temperature range 252–370 K. Pulse radiolysis/transient UV absorption techniques were used to study the ultraviolet absorption spectra and kinetics of $\text{CH}_3\text{OC}(\text{O})\text{OCH}_2$ and $\text{CH}_3\text{OC}(\text{O})\text{CH}_2\text{O}_2$ radicals at 296 K.

The codisposal of trace metals (e.g. Co), synthetic chelates (e.g. ethylenediaminetetraacetic acid, H(4) EDTA) and water-miscible organic solvents has occurred at some contamination sites. The reactions of Co(II)-EDTA with a redox reactive naturally occurring solid, goethite, in aqueous and semiaqueous (methanol-water, acetone-water) suspensions was studied. UV-visible spectroscopy indicated that goethite catalysed oxidation of Co(II)-EDTA to Co(III)-EDTA by dissolved O_2 . These reactions have important implications on the fate of the redox-sensitive metal in complex, mixed waste environments.

Photocatalytic Degradation

A number of organic pollutants present in industrial and domestic wastewater resist biodegradation and they are

poisonous even at low concentrations. A new method for removing toxicants from wastewater is based on the use of photocatalysis. It was found that titanium dioxide (TiO_2) is the best photocatalyst for the detoxification of water because it is cheap, nontoxic and easy to use and handle. The energy gap in TiO_2 is 3.2 eV and thus it can be activated at >400 nm.

The primary oxidant responsible for most advanced oxidation processes, i.e. the use of photochemical methods, is the hydroxyl radical, which is formed by the reduction reactions of electrophiles with water or hydroxide ions. The mechanism of the formation of the hydroxyl radical is well discussed in the literature. Heterogeneous photocatalytic oxidation of organic compounds in aqueous solution is achieved by the reactive hydroxyl radical. The photocatalytic process can remove a large number of organic hazardous compounds in water. Phenols, carboxylic acids and herbicides are among a large number of pollutants, which are destroyed in air and in water using photocatalysis.

Photodegradation of 1,2,3,4-tetrachlorodibenzo-*p*-dioxin (1,2,3,4-TCDD) in hexane solution was studied under controlled near-UV light exposure in the spectral region from 325 to 269 nm. Irradiation experiments carried out at a constant light energy (700 mJ) showed that the percentage of 1,2,3,4-TCDD left in the solution after irradiation changed from about 55 to 75%, with a minimum of 55% at 310 nm. Further irradiation experiments carried out at two wavelengths, namely 310 and 269 nm, and light energy ranging from 0 to 4000 mJ, showed that the photodegradation reaction of the TCDD always followed pseudo-first-order kinetics.

A semitransparent TiO_2 film with extraordinarily high photocatalytic activity was prepared on a glass substrate by sintering a TiO_2 sol at 450 °C. The photocatalytic properties of the film were investigated by measuring the photodegradative oxidation of gaseous acetaldehyde at various concentrations under strong and weak UV light irradiation conditions. The kinetics of acetaldehyde degradation as catalysed by the TiO_2 film as well as by P-25 powder were analysed in terms of the Langmuir–Hinshelwood model. It is shown that the number of adsorption sites per unit true surface area is larger with the TiO_2 film, as analysed in powder form, than with P-25 powder. Meanwhile, the first-order reaction rate constant is also much larger with the film than with P-25 powder. Moreover, under most experimental conditions, particularly with high concentrations of acetaldehyde and weak UV illumination intensity, the quantum efficiency was found to exceed 100% on an absorbed-photon basis, assuming that only photogenerated holes play a major role in the reaction. This leads to the conclusion that the photodegradative oxidation of acetaldehyde is not mediated solely by hydroxyl radicals, generated via hole capture by surface hydroxyl ions or water molecules,

but also by photocatalytically generated superoxide ion, which can be generated by the reduction of adsorbed oxygen with photogenerated electrons.

Solvent Effects and Solvolysis

Oxidations of arylalkanes by $(\text{Bu}_4\text{NMnO}_4)\text{-Bu}^n$ have been studied, e.g. toluene, ethylbenzene, diphenylmethane, triphenylmethane, 9,10-dihydroanthracene, xanthene and fluorene. Toluene is oxidized to benzoic acid and a small amount of benzaldehyde; other substrates give oxygenated and/or dehydrogenated products. The manganese product of all of the reactions is colloidal MnO_2 . The kinetics of the reactions, monitored by UV-visible spectrometry, show that the initial reactions are first order in the concentrations of both $(\text{Bu}_4\text{NMnO}_4)\text{-Bu}^n$ and substrate. No induction periods are observed. The same rate constants for toluene oxidation are observed in neat toluene and in *O*-dichlorobenzene solvent, within experimental errors. The presence of O_2 increases the rate of $(\text{Bu}_4\text{NMnO}_4)\text{-Bu}^n$ disappearance. The reactions of toluene and dihydroanthracene exhibit primary isotope effects; the rates of oxidation of substituted toluenes show only small substituent effects. In the reactions of dihydroanthracene and fluorene, the MnO_2 product is consumed in a subsequent reaction that appears to form a charge-transfer complex. The rate-limiting step in all of the reactions is hydrogen atom transfer from the substrate to a permanganate oxo group. The enthalpies of activation for the different substrates are directly proportional to the ΔH for the hydrogen atom transfer step, as is typical of organic radical reactions. The ability of permanganate to abstract a hydrogen atom is explained on the basis of its ability to form an $80 \pm 3 \text{ kcal mol}^{-1}$ bond to H, as calculated from a thermochemical cycle.

Polymerization

The kinetics of oxidation of a macromolecule, poly(ethylene glycol) [PEG] by ceric sulfate in sulfuric acid medium has been studied by means of UV-visible spectrophotometry. The observed difference in rates of oxidation has been explained in terms of cage formation. The oxidation of PEG proceeded without the formation of a stable intermediate complex. The order with respect to the concentrations of PEG and ceric sulfate has been found to be one and the overall order is two. The effects of acid concentration, sulfate ion concentration, ionic strength and temperature on the rate of the oxidation reaction have been studied. The thermodynamic parameters for the oxidation reaction have also been presented. Based on the experimental results, a suitable kinetic expression and a plausible mechanism have been proposed for the oxidation reaction.

Reaction of *trans*-1,3-diphenyl-1-butene the *trans* ethylenic dimer of styrene, with trifluoromethanesulfonic

acid in dichloromethane has been performed at temperatures lower than room temperature using a stopped-flow technique with real time UV-visible spectroscopic detection. The main product of the reaction was the dimer. A transient absorption at 340 nm has been assigned to 1,3-diphenylbutylium, a model for the polystyryl cation. Other absorptions at 349 and 505 nm have also been observed and were assigned to an allylic cation, 1,3-diphenyl-1-buten-3-ylum, resulting from hydride abstraction from D. This species was very stable at temperatures lower than -30°C . A general mechanism was proposed based on a kinetic study of the reactions involved.

Determination of Metals and Molecules at Low Concentration

A simple method for measuring peroxides in a single living cell has been developed, and the generation of peroxides upon ultraviolet (UV) irradiation was measured in human and pig pidermal keratinocytes. The method was based on the fact that the nonfluorescent dye dihydrorhodamine 123 reacts in the presence of peroxides, such as H_2O_2 , and changes into fluorescent rhodamine 123, and hence the fluorescence intensity is proportional to the amount of reacted peroxide. The epidermal keratinocytes were loaded with the dihydrorhodamine under a fluorescence microscope and exposed to UV radiation. Taking C as the content of peroxides generated within the cell and I as the increase influence (radiation intensity $\times$ time = photons cm^{-2}), the following empirical relationship was established: $C = C_s (1 - \exp^{-kI})$, where C_s is the content of peroxides at the saturation state, and k is a kinetic parameter. The dependence of the two parameters on wavelength in the range 280–400 nm was studied. In human keratinocytes C_s had a peak at 310 nm and a small peak (shoulder) at 380 nm, while k increased gradually towards shorter wavelengths. In pig keratinocytes, on the other hand, k had a peak around 380 nm and a shoulder at 330 nm, while C_s remained unchanged. Aminotriazole, an inhibitor of catalase, and low temperatures increased the stationary levels of peroxide generation in pig keratinocytes upon UV irradiation, indicating that the reaction used for measuring intracellular peroxides is competitive with the intrinsic reactions in scavenging peroxides.

A simultaneous EPR and visible spectrophotometric study is reported on the interaction of the stable free radical 1,1-diphenyl-2-picrylhydrazyl (DPPH) dissolved in ethanol with thioglycolic acid ($\text{HSCH}_2\text{CO}_2\text{H}$, TGA). The results of the kinetic studies at room temperature allow the assumption of 1:1 stoichiometry of the reaction between DPPH and TGA, giving 1,1-diphenyl-2-picrylhydrazine (DPPH) and thioglycolic disulfide. The linear plots of EPR and UV-visible responses versus

the quantity of added TGA are used to find the DPPH molar absorptivity at 520 nm to be $12350 \pm 3\%$ $1 \text{ mol}^{-1} \text{ cm}^{-1}$ which may be used as a criterion for the purity of the material itself. It was also found that the paramagnetic and optical properties of a 30-year-old sample gave results suggesting that in the solid state DPPH is a fairly stable material.

Reaction Kinetics, Substitution Effects, Structure–Reactivity Relationships

The kinetics of the addition of arenesulfinic acids to 4-substituted 2-nitroethenylarenes was studied by means of UV spectrophotometry. The effect of 4-substituting groups in benzenesulfinic acids, and the change in reactivity of the nitroethylene system due to typical electron-donating and electron-withdrawing groups were investigated. The substituent effect on benzenesulfinic acid fits Hammett's equation, ρ -value at 298 K being -1.12 . Kinetic studies were carried out at 288–308 K, and the activating energy and the enthalpy of activation were determined.

The kinetics of the addition of unsubstituted and substituted benzenesulfinic acids to various 2-halogeno-nitroethenylarenes was studied by means of UV spectroscopy. The effect of 4-substituents in benzenesulfinic acids and the change in reactivity of the nitroethylene system in 2-halogeno-2-nitroethenyl-arenes in the presence of various substituents in the benzene ring and various halogens at the double bond were investigated. Kinetic studies were made at 288–308 K, and the activating energy and enthalpy of activation were determined.

Effect of pH, Pressure, Temperature and Ionic Strength on Reaction Kinetics

The degradation kinetics of xanthate in homogeneous solution as a function of pH at 5°C , 20°C and 40°C was systematically studied by UV-visible spectrophotometric measurements. The results indicate that the degradation of ethyl xanthate is rapidly increased with decreasing pH at $\text{pH} < 7$. At pH 7–8, the maximum half-life of the xanthate appears. The degradation was faster at pH 9–10, but at $\text{pH} > 10$ the half-lives of xanthate once again increase. The investigations were also extended to different media other than pure water, such as 0.1 M NaClO_4 , 0.1 M NaNO_3 , 0.1 M NaCl as well as in the supernatants of flotation tailings of sulfide minerals. The rate constants of xanthate degradation were calculated and presented together with half-lives and activation energies of xanthate degradation. The degradation products and reaction mechanisms are discussed based on experimental results.

The kinetics of the association reaction of the phenoxo radical with NO were investigated using a flash

photolysis technique coupled to UV absorption spectrometry. Experiments were performed at atmospheric pressure, and theoretical calculations showed that the rate constant is at the high-pressure limit above 50 torr (6.7×10^3 Pa) for temperatures below 400 K. Upon increasing the temperature, the reaction was found to be reversible, and the equilibrium kinetics have been studied at seven temperatures between 310 and 423 K.

Validation of Molecular Orbital Calculations

The suitability of Gaussian distribution functions to describe the shape and temperature dependence of the UV absorption continua of peroxy radicals has been investigated. The ethylperoxy radical was used as a test case. Its 298 K absorption continuum was found to be best described by a semilogarithmic Gaussian distribution function. A linear Gaussian distribution function performed less well but still adequately described the continuous absorption. The temperature dependence of the ethylperoxy radical UV absorption continuum was also well predicted. Analogous results obtained for the methylperoxy radical support these conclusions. A theoretical comparison of the semilogarithmic and linear Gaussian distribution functions is given and a potential energy diagram of the ethylperoxy radical derived. The experimentally determined absorption cross-sections of HO_2 have been reanalysed. It is shown that either the measurements at short wavelengths are in error or an unidentified electronic transition of HO_2 exists.

Enzymatic Reactions

A one-step spectrophotometric method for monitoring nucleic acid cleavage by ribonuclease H from *E. coli* and

type II restriction endonucleases has been proposed. It is based on recording the increase in the UV absorbance at 260 nm during the course of enzymatic reaction. Duplexes stable under the reaction conditions were chosen as substrates for the enzymes being studied. In order to obtain duplex dissociation following their cleavage by the enzyme appropriate temperature conditions were selected. The spectrophotometric method may be applied for rapid testing of the nuclease activity in protein preparations as well as for precise quantitative analysis of nucleic acid degradation by enzymes. This method may be successfully employed in kinetic studies of nucleic acid–protein interactions.

Symbols

a	distance of closest approach between the paramagnetic centre and the diffusing solvent molecules
D	relative solute–solvent diffusion coefficient
H	hyperfine shift
H_S	hyperfine shift scalar coupling
H_D	hyperfine shift dipole coupling
K_i	interaction constant between LSR and S
K_1 and K_2	coefficients related to anisotropy of magnetic susceptibility tensor
K_A	association constant
n	number of independent sites characterized by a given K_A value
q	number of interacting sites
r_i	distance between nucleus and paramagnetic ion
r_i, θ_i and Ω_i	spherical coordinates of i nucleus in the reference frame of the principal magnetic susceptibility tensor
R_1^0	relaxation rate in absence of paramagnetic compound
R_{1p}^{os}	diffusion-controlled contribution to relaxation rate from water molecules in the outer coordination sphere of the paramagnetic centre
R_{1p}^{is}	paramagnetic contribution to relaxation rate due to exchange of water molecules in the inner coordination sphere with those in the bulk
R_{1p}^b	solvent–water relaxation in the all-bound limit
S	substrate
T_{1M}	relaxation time of the protons of the water molecule in the first coordination sphere of the complex
T_1	spin-lattice relaxation time
χ^b	molar fraction of macromolecular adduct
Δ_I^{LSR-S}	all-bound shift of the LSR-S complex
$\Delta\delta_i$	observed LSR-induced shifts
$\Delta\Delta\delta$	enantiomeric shift difference between the $\Delta\delta$ LIS for R and S configuration

ε^*	enhancement factor
ϕ	angle between r_i vector and Ln–lig- and bond or rotation axis
γ_H and γ_S	electron and proton magnetogyric ratios
ρ	LSR to S ratio
$\tau_{c1, 2}$ and τ_e	relevant correlation times for time-dependent dipolar and contact interactions
τ_M	residence lifetime of the water molecule in the first coordination sphere of the complex
τ_R	reorientational correlation time
τ_{S1} and τ_{S2}	longitudinal and transverse electron spin relaxation times
ω_H and ω_S	proton and electron Larmor frequencies

Introduction

Chemical shift and relaxation reagents are substances that, when added to the systems under study, enable the spectroscopist to tackle a specific problem of spectral assignment, stereochemical determination or quantitative measurement. They are usually represented by paramagnetic compounds, and their effects may be exploited by the solute and the solvent, manifested as large shifts or pronounced relaxation enhancement of the lines. Both effects reflect the response of the nuclear dipole to the local magnetic field of an unpaired electron in the reagent, whose magnetic moment is 658.21 times higher than that of the proton.

A knowledge of the basic theory of the paramagnetic interaction is useful to pursue a better exploitation of the effects induced by the paramagnetic perturbation.

In principle, the interaction of a nucleus with an unpaired electron (hyperfine interaction) has the same nature as a nucleus–nucleus interaction, it is determined by a direct, through-space dipole–dipole coupling (H_D) and an indirect, through-bonds contact (scalar) coupling (H_S):

$$H = H_D + H_S$$

The hyperfine shift arises from components present in both terms which are invariant with time in the external

magnetic field; these contributions are indicated as 'dipolar' or 'pseudocontact' shifts when resulting from dipolar interactions and 'Fermi' or 'contact' shifts when resulting from scalar interactions, respectively. The time-dependent fluctuations in either term will result in nuclear relaxation ('dipolar' and 'scalar' relaxation, respectively). Although, in theory, correct expressions for H_D and H_S can be derived, the elusive nature of the orbiting electrons and the number of their interactions make it very difficult to develop an accurate theory for shift and relaxation promoted by paramagnetic substances. In general one may conclude that, while measurements of the effects promoted by paramagnetic species are easy, interpretation of data is difficult.

According to their dominant effect on the NMR spectra of surrounding nuclei, paramagnetic reagents can be classified as chemical shift or relaxation reagents. Organic free radicals and metal ions with isotropic electron density, such as Mn^{2+} (five electrons in five d orbitals) or Gd^{3+} (seven electrons in seven f orbitals) do not give rise to pseudocontact shifts and are commonly regarded as relaxation probes. However, anisotropic ions with short electron relaxation times, such as all other lanthanide ions, can be referred to as chemical shift probes. Species such as Ni^{2+} , Fe^{3+} and Cr^{3+} give rise to both effects and defy classification.

Chemical Shift Reagents

In 1969, Hinckley suggested that the use of paramagnetic lanthanide complexes might be very useful to simplify unresolved 1H , NMR resonances, thus allowing otherwise intractable spectra to be easily interpreted (Figure 1). Although the introduction of high-field magnets and two-dimensional methods have largely reduced the need for such qualitative use of 'lanthanide-induced shift' (LIS) measurements, the exploitation of the large local fields generated by some lanthanide ions is still an item of strong interest in several areas of NMR applications.

When a substrate interacts with the lanthanide complex, it magnetically active nuclei *feel* the presence of the unpaired f electrons; their LIS is basically determined by two properties of the lanthanide complex, namely (1) its Lewis acid behaviour and (2) the number of unpaired electrons. The commercially available lanthanide shift reagents (LSRs) are mainly tris(β -diketonate) complexes, having the 2, 4-pentanedione chelate structure (Table 1). These neutral complexes are soluble in organic solvents and they promptly form acid-base adducts with substrates endowed with Lewis base behaviour. In fact alcohols, ethers, amines and nitriles reversibly interact with the LSR to form paramagnetic adducts whose 1H NMR shifts may be far away from the diamagnetic

Figure 1 Simplification of the low-field 1H NMR spectrum of 1-pentanol by $Eu(thd)_3$. The clustered signals of the methylene chain are totally separated into clearly defined multiplets. (a) normal spectrum; (b) after addition of $Eu(thd)_3$.

thd = tris(2,2,6,6-tetramethyl-3, 5-heptanedionato);

dpm = tris(dipivaloylmethanato);

pta = tris(1,1,1-trifluoro-5,5-dimethyl-2,4-hexanedionato);

tfn = tris(1,1,1,2,2,3,3,3,7,7,8,8,9,9,9-tetradecafluoro-4,6-nonanedionato);

fhd = tris(1,1,1,2,2,6,6,7,7,7-decafluoro-3,5-heptanedionato);

dfhd = tris(1,1,1,2,2,3,3,3,7,7,7-decafluoro-4,6-heptanedionato);

fod = tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedionato).

values. As the substrate B in fast exchange between the LSR-bound and free forms, the effect will be averaged on all the molecules of the substrate. The resulting shifts will depend upon the strength of the interaction, the geometry of the adduct and the LSR to substrate ratio.

The acid character of the lanthanide chelate and the donor and steric properties of the substrate define the strength of the acid–base adduct. Usually more stable complexes are found as the ionic radius of the metal decreases. Fluorinated diketonates increase the Lewis acidity of the lanthanide ion with respect to the protonated derivatives. This explains why $\text{Eu}(\text{fod})_3$ (see Table 1) is the mostly commonly used LSR.

Contributions to the LIS

The shift induced by the lanthanide ion on the resonances of the organic substrate results from three contributions.

- A diamagnetic term corresponding to the coordination shift. On ^1H resonances it is usually upfield and rather small.
- The contact or Fermi term which depends on the delocalization of unpaired electron density on the substrate nuclei and has then been related to the value of the hyperfine coupling constant.
- The dipolar or pseudocontact term which depends on the spatial proximity of a given nucleus to the paramagnetic centre and on the anisotropy of the magnetic susceptibility tensor. To extract structural information from LIS data there has to be an accurate determination of the latter term.

The first step in the procedure consists of the determination of the all-bound shifts $\Delta_i^{\text{LSR-S}}$. In the presence of the equilibrium between the substrate (S) and the LSR

the observed $\Delta\delta_i$ are proportional to the term $([\text{LSR-S}]/[\text{S}])\Delta_i^{\text{LSR-S}}$. Thus $\Delta\delta_i$ are measured for various LSR to S ratios (ρ) and graphs are obtained by plotting the observed shifts $\Delta\delta_i = \delta_i^{\text{obs}} - \delta_i^{\circ}$ (where δ_i° is the chemical shift measured in the absence of the LSR or, better, in the presence of diamagnetic La or Lu analogue) as a function of ρ .

If an axial symmetry of the dipolar magnetic field in the LSR–S adduct is assumed, the dipolar shifts are proportional to the term $(3 \cos^2\phi - 1)/r_i^3$. In this case, the principal magnetic axis of the lanthanide is taken as collinear with the lanthanide–ligand bond. r_i is the distance between a given nucleus and the paramagnetic ion and ϕ is the angle between the r_i vector and the

Ln–ligand bond. Many systems have been successfully investigated on the basis of this simplifying assumption. The occurrence of axial symmetry is justified as a result of time averaging effects. This means that the fast rotation of the substrate along the coordination axis introduces an effective axial symmetry, where ϕ now refers to the angles between r_i and the rotation axis rather than the actual symmetry axis.

In the more general case of a rhombic, non-axial symmetry, the dipolar contribution to the (all-bound) LIS is described as follows:

$$\Delta_i^{\text{LSR-S}} = K_1 \frac{(3 \cos^2\theta_i - 1)}{r_i^3} + K_2 \frac{\sin^2\theta_i \cos 2\Omega_i}{r_i^3}$$

where r_i , θ_i and Ω_i are the usual spherical coordinates of the i nucleus in the reference frame of the principal magnetic susceptibility tensor. K_1 and K_2 are coefficients related to the anisotropy of the magnetic susceptibility tensor. Several computer programs have been written to find the molecular geometry that best fits the set of experimental Δ_i values.

A decrease in temperature causes an increase in the lanthanide-induced chemical shifts, which usually provides an enhanced resolving power of the LSR. This behaviour results (1) from an increase of the concentration of the adduct and (2) from the temperature dependence of the paramagnetic shift (the dipolar shift shows a $1/T^2$ dependence, whereas the contact term displays a $1/T$ dependence).

Diketones are insoluble in water. Diglycolates have been proposed as substitutes for studies in aqueous solutions. Another possibility is the use of lanthanide aquo-ions, and perchlorates and nitrates have been used in several cases: they are soluble at $\text{pH} < 6$ and provide good shifts for a number of anionic functions. Finally, good results in aqueous solutions have been obtained by using EDTA chelates which work at pH values as high as 10.

Chiral Shift Reagents

It is well established that a method to distinguish enantiomers by NMR is to convert them into diastereoisomers by means of appropriate optically active reactants. Thus it was suggested that the use of chiral LSR (LSR^*) can induce shift differences in the spectra of enantiomers:

R and S give the same NMR spectrum as they are mirror images, whereas $\text{LSR}^* - \text{R}$ and $\text{LSR}^* - \text{S}$ are diastereoisomers and then are characterized by different NMR properties. In the presence of fast exchange between free and bound forms, R and S will give rise to different

signals as they represent average values between the free and the bound forms. The enantiomeric shift difference between the $\Delta\delta$ LIS for the R and S configuration is usually indicated as $\Delta\Delta\delta$. The observed $\Delta\Delta\delta$ values depend on the equilibrium constants for the formation of the labile complexes between the enantiomers and the chiral reagent, and on the shift differences between the diastereomeric complexes.

The first chiral LSR was reported by Whitesides and consisted of a camphor-based Eu^{3+} complex. Since then, several chiral LSR* have been proposed and many of them are commercially available (Figure 2 and Table 2).

In some cases, it has been found that enantiomeric resolution has been obtained also with the use of an achiral reagent such as $\text{Eu}(\text{fod})_3$. This behaviour has been explained in terms of the formation of ternary 1:2 adducts which are no longer mirror images (such as LSR-R-R and LSR-R-S). In principle, another explanation may be possible on the grounds that $\text{Eu}(\text{fod})_3$ may be considered as a racemic mixture of enantiomers.

LSR for Alkali Metal Ions

An interesting extension of the use of LSR deals with the separation of the resonances of $^7\text{Li}^+$, $^{23}\text{Na}^+$ and $^{39}\text{K}^+$ present in different biological compartments. Such

Figure 2 ^1H NMR spectra of α -phenylethylamine in CCl_4 after addition of tris[(3-*tert*-butylhydroxymethylene)-*D*-camphorato]-europium^{III}. Molar ratio LSR* to substrate 0.5: (a) S-form; (b) racemic mixture.

NMR-active metal cations are of clinical importance, but from their routine NMR spectra it is not possible to distinguish whether they are in the intra- or the extra-cellular compartments. The addition of a paramagnetic complex that selectively distributes in one compartment only can remove such signal degeneracy. In fact, the interaction with the paramagnetic species induces a shift in other resonances of the alkaline ions present in the same compartment as the LSR (Figure 3). Up to now in laboratory practice, four complexes have been studied in detail and applied to answer several questions of biomedical interest: the Dy(III) complexes of PPP^{5-} (triphosphate) and TTHA^{6-} (triethylenetetraamine-hexaacetate) and the Dy(III) and Tm(III) complexes of DOTP^{5-} (tetraazacyclododecane-*N*, *N'*, *N''*, *N'''* tetrakis (methylenephosphonate)).

The most effective reagent so far reported is the chelate $\text{Dy}(\text{PPP})_2^{7-}$, first introduced by Gupta and Gupta in 1982. However, this metal complex has been proved to present several disadvantages that prevent its use in living animals or humans. First of all it is rather toxic, probably due to irreversible ligand dissociation promoted *in vivo*, with subsequent release of the metal ion. Furthermore, the complex is involved in several protonation equilibria and shows competition with endogenous divalent cations (Mg^{2+} , Ca^{2+}) which reduces its resolution ability. The $\text{Dy}(\text{TTHA})^{3-}$ complex is much less toxic, as a consequence, probably, of the high stability constant of Dy^{3+} with this multidentate ligand.

Figure 3 ^{23}Na NMR spectra at 2.1 T and 39°C of whole human blood before (a) and after (b) the addition of $\text{Dy}(\text{DOTP})^{5-}$ (5 mM). Intra- and extracellular sodium resonances are resolved.

However, the reduced value of the negative charge on the complex and the fact that it is mainly localized on unbound carboxylic groups, away from the paramagnetic centre, makes this metal chelate less effective in removing the signal degeneracy. This implies that higher doses of the LSR are needed for an optimum resolution. The $\text{Dy}(\text{III})$ and $\text{Tm}(\text{III})$ complexes of DOTP represent an important improvement in the search for safe and effective LSRs for metal cations of biological relevance. In fact, these metal chelates are extremely resistant to dissociation processes over a wide range of pH and show axial symmetry and interaction sites for the cations very close to their 4-fold axis of symmetry, which ensures a maximum shifting efficiency. Indeed $\text{Dy}(\text{DOTP})^{5-}$ produces a magnitude of shift analogous to that observed for $\text{Dy}(\text{PPP})_2^{7-}$ at the same concentration. However, the efficiency of the $\text{Dy}(\text{III})$ chelate has been shown to be markedly quenched by stoichiometric amounts of Ca^{2+} , and thus the $\text{Tm}(\text{III})$ complex, less sensitive to these effects, has found wider applications.

In conclusion, it is worth commenting that, although several studies have been possible by the use of the available LSRs, much remains to be done in terms of synthetic strategy and ligand design in the search for safer and more effective compounds.

Relaxation Reagents

An alternative exploitation of paramagnetic complexes as auxiliary NMR reagents deals with their effect on the relaxation of substrate nuclei. Indeed, in the presence of a

Figure 4 ^{13}C NMR spectra (a) and integrated intensities (b) of a $\text{Fe}(\text{CO})_5$ sample with different added concentrations of $\text{Cr}(\text{acac})_3$. Different symbols refer to independent measurements.

relaxation reagent the electron–nucleus relaxation may easily become so efficient that it predominates over the intrinsic relaxation processes of a given nucleus. Such effects may be exploited either on the solute or on the solvent resonances. A number of applications based on the use of relaxation reagents have been reported, ranging from structural assignments to nuclear Overhauser effect (NOE) quenchers for correct intensity measurements, from the assessment of the binding to proteins to the separation of resonances from different compartments. A particularly important class of relaxation reagents is represented by the contrast agents for magnetic resonance imaging (MRI).

The first example dealing with the use of paramagnetic species to shorten the relaxation time of the solvent nuclei deals with the very first detection of the NMR phenomenon, as Bloch used iron(III) nitrate to avoid saturation of the water proton signal. Then in the 1970s it was rather common, in organic and organometallic chemistry, to add to the substrate solution a reagent such as $\text{Cr}(\text{acetylacetonate})_3$ ($\text{Cr}(\text{acac})_3$) or $\text{Fe}(\text{acac})_3$ to shorten the T_1 of ^{13}C and ^{15}N resonances without broadening the signal. In **Figure 4** the ^{13}C intensities of the $\text{Fe}(\text{CO})_5$ signal, measured at 2.1 T, in the presence of variable amounts of $\text{Cr}(\text{acac})_3$, are reported. At this field the T_1 value of the ^{13}CO groups is very long as it is determined by the chemical shift anisotropy term; by increasing the magnetic field strength it becomes markedly shorter. Thus, the availability of high magnetic fields has limited to some extent the use of relaxation reagents for the purpose of an overall shortening of the relaxation times.

The presence of a relaxation reagent induces a dominant relaxation path for all the resonances of a given

substrate present in solution and this may be exploited for quantitative NMR determinations. In fact, this method eliminates the problems associated with a correct intensity measurement when the various resonances are endowed with different relaxation times and different NOE enhancements.

Another application of relaxation reagents deals with the selective removal of a given spin-coupling pattern, that is the interaction with a paramagnetic reagent produces a so-called chemical decoupling mechanism. In fact, in an AX-coupled system the multiplicity of each resonance may be removed when the mean lifetime of the coupled nucleus in a given state (α or β) becomes shorter than the inverse of the coupling constant J_{AX} . Therefore, the occurrence of efficient relaxation induced by the paramagnetic reagent causes the removal of the effective coupling.

Theory of Paramagnetic Relaxation

The quantitative description of relaxation effects induced by paramagnetic species presents theoretical problems that are far from trivial. However, it is customary to resort to the simplified approach developed by Solomon and Blombergen to account for the relaxation enhancement of solvent nuclei of aqueous solutions of paramagnetic metal ions. On the basis of this approach the observed solvent relaxation rate is given by the sum of three contributions:

$$R_1^{\text{obs}} = R_1^{\text{is}} + R_{1\text{p}}^{\text{os}} + R_1^{\text{o}}$$

where R_1^{o} is the relaxation rate in the absence of the paramagnetic compound, $R_{1\text{p}}^{\text{is}}$ represents the paramagnetic contribution due to the exchange of water molecules in the inner coordination sphere with water molecules in the bulk, and $R_{1\text{p}}^{\text{os}}$ is the diffusion-controlled contribution from water molecules in the outer coordination sphere of the paramagnetic centre. In the absence of a coordinative interaction between the paramagnetic metal ion and the substrate-solvent molecules, only the latter term contributes to the observed paramagnetic relaxation enhancement. In this case the relaxation enhancement is exclusively due to the electron-nucleus dipolar interaction between the metal ion and the solvent molecules diffusing in the outer coordination sphere of the complex. This interaction is modulated by the translational diffusive motion of solute and solvent and by the electronic relaxation time. An analytical expression for this contribution has been derived by Freed and co-workers in a study of the relaxation enhancement of solvent molecules in solutions containing stable nitroxide radicals.

$$R_{1\text{p}}^{\text{os}} = C^{\text{os}} \left(\frac{1}{aD} \right) [7J(\omega_S) + 3J(\omega_H)]$$

In this expression, C^{os} is constant for a given observed nucleus, a is the distance of closest approach between the paramagnetic centre and the diffusing solvent molecules and D is the relative solute-solvent diffusion coefficient. The dependence on the electronic relaxation time is expressed by the non-Lorentzian spectral density functions $J(\omega)$.

As far as the inner sphere contribution is concerned, $R_{1\text{p}}^{\text{is}}$ is determined by the relaxation time $T_{1\text{M}}$ of the nuclei of the substrate-solvent complex and by its lifetime τ_{M} , weighted by the molar ratio of the bound substrate-solvent:

$$R_{1\text{p}} = \frac{[\text{C}]}{[\text{S}]} q \frac{1}{T_{1\text{M}} + \tau_{\text{M}}}$$

where $[\text{C}]$ is the molar concentration of the paramagnetic reagent, q is the number of interacting sites, and $[\text{S}]$ is the concentration of the substrate-solvent complex. In the case of dilute water solutions, when the relaxation enhancement is observed on the solvent nuclei, $[\text{S}] = 55.54 \text{ M}$.

The $T_{1\text{M}}$ value in the paramagnetic reagent-substrate adduct is determined by (1) the dipolar interaction between the observed nucleus and the unpaired electron(s) and (2) the contact interaction between the magnetically active nucleus and the unpaired electron density localized in the position of the nucleus itself. An analytical form is given by the Solomon-Bloembergen equation (here for T_1 ; an analogous expression is derived for T_2):

$$\frac{1}{T_{1\text{M}}} = \frac{2}{15} \left(\frac{\mu_0}{4\pi} \right) \frac{\hbar^2 \gamma_S^2 \gamma_H^2}{\tau^6} S(S+1) \times \left[\frac{3\tau_{c1}}{1 + \omega_H^2 \tau_{c1}^2} + \frac{7\tau_{c2}}{1 + \omega_S^2 \tau_{c2}^2} \right] + \frac{2}{3} S(S+1) \left(\frac{A}{\hbar} \right)^2 \times \left(\frac{\tau_e}{1 + \omega_S^2 \tau_e^2} \right)$$

where S is the electron spin quantum number, γ_H and γ_S are proton and electron magnetogyric ratios, respectively, r is the distance between the metal ion and the given nucleus of the coordinated substrate, ω_H and ω_S are the proton and electron Larmor frequencies, respectively. $\tau_{c1,2}$ and τ_e are the relevant correlation times for the time-dependent dipolar and contact interactions, respectively:

$$\frac{1}{\tau_{c1,2}} = \frac{1}{\tau_R} + \frac{1}{\tau_M} + \frac{1}{\tau_{S1,2}}$$

$$\frac{1}{\tau_e} = \frac{1}{\tau_{S1}} + \frac{1}{\tau_M}$$

where τ_R is the reorientational correlation time and τ_{S1} and τ_{S2} are the longitudinal and transverse electron spin relaxation times.

The contact term is often negligible, especially when dealing with a paramagnetic ion bound to a macro-molecule because the hyperfine coupling constant $A/\hbar$ is

in the MHz range, whereas the coefficient of the dipolar term is one order of magnitude larger.

The Protons Relaxation Enhancement (PRE) Method

Upon interacting with a macromolecule the relaxation induced by a paramagnetic species usually displays remarkable changes, primarily related to the increase of the molecular reorientational time τ_R on going from the free to the bound form. This may result in a strong increase of the R_{1p}^{is} term, from which it is possible to assess the affinity (and the number of binding sites) between the interacting partners. Quantitatively, in the presence of a reversible interaction between the paramagnetic species and the macromolecule, the observed enhancement depends on both the molar fraction of the macromolecular adduct χ^b and the solvent–water relaxation in the all-bound limit R_{1p}^b . The increase in the relaxation rate is expressed by the enhancement factor ε^* :

$$\varepsilon^* = \frac{R_{1p}^*}{R_{1p}} = \frac{(R_{1p}^{obs} - R_{1p}^*)}{(R_{1p}^{obs} - R_{1p}^*)}$$

The asterisk indicates the presence of the macromolecule in solution. The enhancement factor ranges from 1 (no interaction) to $\varepsilon^b = R_{1p}^b/R_{1p}$ in the all-bound limit (strong excess of macromolecule).

$$\varepsilon^* - 1 = \chi^b(\varepsilon^b - 1)$$

The determination of the binding parameter K^A (association constant) and n (number of independent sites characterized by a given K_A value) from the mass action law is straightforward. Given the association equilibrium between the metal complex M and the protein (enzyme) E,

$$K_A = \frac{[ME]}{[M]_f[E]_f} = \frac{[ME]}{([M]_t - [ME])([E]_t - [ME])}$$

$$\varepsilon^* = \chi^b \varepsilon^b + (1 - \chi^b) = \frac{[ME]}{[M]_t} \varepsilon^b + \frac{[M]_t - [ME]}{[M]_t}$$

where n time $[E]$ gives the concentration of each class of sites on the macromolecule. Superscript b and subscripts f and t indicate bound, free and total, respectively.

The experimental procedure consists of the determination of the enhancement factor ε^* through two distinct titrations. In the first titration, a rectangular hyperbola describing the change of ε^* as the $[E]_t$ to $[M]_t$ ratio increases is reported (Figure 5). The treatment of the obtained binding isotherm yields the value of ε^b and the product nK_A . In the second titration, the

Figure 5 Direct (a) and inverse (b) PRE titrations: by plotting ε^* vs. macromolecule concentration a rectangular hyperbola is obtained, whose analysis yields the ε^b value together with the nK_A product. The Scatchard's plot obtained from the inverse titration allows the determination of n and K_A separately.

behaviour of ε^* is monitored at fixed macromolecule concentration by changing the metal complex concentration. Results are conveniently expressed in the form of a Scatchard's plot:

$$r/[M]_f = nK_A - rK_A$$

The value of r may easily be calculated once the all-bound enhancement ε^b is known. In the same way, the free $[M]_f$ concentration is obtained from the total $[M]_t$ complex concentration.

$$r = \frac{(\varepsilon^* - 1)[M]_t}{(\varepsilon^b - 1)[E]_t}$$

$$[M]_f = \left(1 - \frac{\varepsilon^* - 1}{\varepsilon^b - 1}\right)[M]_t$$

By plotting $r/[M]_f$ vs. r , a straight line is obtained whose x -axis intercept gives the n value and whose slope is equal to $-K_A$.

Contrast Agents for MRI

MRI, one of the most powerful tools in modern clinical diagnosis, is based on the topological representation of NMR parameters such as proton density and transverse and longitudinal relaxation times. Differences in these

Figure 6 Male patient, 54 year old, 67 kg with multiple hepatic metastases from a neuroendocrine tumour of the pancreas: images are taken before (a) and 90 minutes after (b) intravenous administration of 0.1 mmol kg^{-1} of a liver-specific Gd^{3+} chelate.

parameters allow impressive anatomical discrimination to be made, and make it possible to distinguish pathological from healthy tissues. The potential of MRI is further strengthened by the use of suitable contrast agents (CAs), compounds that are able to alter markedly the magnetic properties of the region where they are distributed. Among them, paramagnetic Gd^{3+} complexes (seven unpaired electrons) are the most used because of their ability to enhance the proton relaxation rates of solvent water molecules (**Figure 6**). Their use provides the physicians with further physiological information to be added to the impressive anatomical resolution commonly obtained in the uncontrasted images. Thus, administration of Gd-based contrast agents has entered into the pool of diagnostic protocols and is particularly useful to assess organ perfusion and any abnormalities in the blood–brain barrier or in kidney clearance. Several other applications, primarily in the field of angiography and tumour targeting, are available in clinical practice. The percentage of MRI investigations using Gd agents is predicted to increase further following the development of more effective and specific contrast media than those currently available.

To be used as a CA for MRI, a Gd^{3+} complex must fulfil two basic requirements: (1) it must have at least one coordinated water molecule in fast exchange (on the NMR relaxation timescale) with the solvent bulk, and (2) the Gd^{3+} ion must be tightly chelated to avoid the release of the metal ion and the ligand which are both

Figure 7 Schematic structure of the Gd^{3+} chelates used in clinical practice. DOTA = 1,4,7,10-tetraazacyclododecane- N,N',N'',N''' -tetraacetic acid; DTPA = diethylenetriaminepentaacetic acid; HPDO3A = N''' -(2-(1-hydroxypropyl))-1,4,7,10-tetraazacyclododecane- N,N',N'' -triacetic acid; DTPABMA = N,N'' -bis(N -methylcarbamoylmethyl)-diethylenetriamine- N,N',N'' -triacetic acid.

potentially harmful. **Figure 7** reports the schematic structures of four ligands whose Gd^{3+} chelates are currently used as CAs for MRI. The overall PRE of water protons ($R_{1p}^{\text{is}} + R_{1p}^{\text{os}}$, see section ‘Theory of paramagnetic relaxation’) referred to a 1 mM concentration of Gd^{3+} chelate is called *millimolar relaxivity* (hereafter *relaxivity*). At the magnetic field strength currently employed in MRI applications, the relaxivity of a Gd^{3+} complex is roughly proportional to its molecular weight, that is it is determined by the value of the molecular reorientational time τ_R . It follows that the search for high relaxivities has concentrated on systems endowed with slow tumbling motion in solution. This condition may be met either (1) by linking a Gd^{3+} chelate to high molecular weight substrates like carboxymethylcellulose, polylysine or dendrimers, etc. or (2) by forming non-covalent adducts with serum albumin. In the latter case, the Gd^{3+} chelates are designed to introduce on the surface of the ligand suitable functionalities able to strongly interact with the serum protein. In addition to providing high relaxivities (which, in turn, allows the administered doses of CA to be reduced) the formation of adducts between Gd^{3+} complexes and albumin are of interest for the design of novel angiographic experiments for which a reduced clearance time and a better compartmentalization in the circulating blood is required.

All interactions involving light with chiral molecules discriminate between the two possible circular polarizations (left=L and right=R). In the absence of a perturbing static electric or magnetic field, the light emitted by a molecular chromophore will be partially circularly polarized if the emitting species is *chiral* or *optically active*. In this context these two terms have identical meaning, and describe a molecular structure in which the mirror image isomers (enantiomers) are not superimposable. The experimental technique of analysing the extent of circular polarization in the light emitted from chiral molecules has been variously referred to as circularly polarized emission (CPE), emission circular intensity differentials (ECID), or circularly polarized luminescence (CPL). In this article the acronym CPL is used to describe this spectroscopic technique. In addition, it will not be necessary in the discussion presented here to use the more specific terms of circularly polarized fluorescence or circularly polarized phosphorescence. Although CPL and circular dichroism (CD) spectroscopy, that is the difference in absorption of left versus right circular polarization, share many common characteristics, they differ from one another in two main ways. First, due to the Franck–Condon principle, CPL probes the chiral geometry of the excited state in the same way that CD probes the ground state structure,

and second, CPL measurements reflect molecular motions and energetics that take place between the excitation (absorption) and emission. Both of these effects have been exploited in CPL measurements, and will be a major focus of what is presented here.

Circularly Polarized Luminescence Transition Probabilities

In CPL spectroscopy one is interested in measuring the difference in the emission intensity (ΔI) of left circularly polarized light (I_L) versus right circularly polarized light (I_R). By convention this difference is defined as follows:

$$\Delta I \equiv I_L - I_R \quad [1]$$

Just as in ordinary luminescence measurements, the determination of absolute emission intensities is quite difficult, so it is customary to report CPL measurements in terms of the ratio of the difference in intensity, divided by the average total luminescence intensity.

$$g_{\text{lum}} = \frac{\Delta I}{\frac{1}{2} I} = \frac{I_L - I_R}{\frac{1}{2} (I_L + I_R)} \quad [2]$$

g_{lum} is referred to as the luminescence dissymmetry ratio (or factor). The extra factor of $\frac{1}{2}$ in eqn [2] is included to make the definition of g_{lum} consistent with the previous definition of the related quantity in CD, namely, g_{abs} .

$$g_{\text{abs}} = \frac{\Delta \varepsilon}{\varepsilon} = \frac{\varepsilon_L - \varepsilon_R}{\frac{1}{2} (\varepsilon_L + \varepsilon_R)} \quad [3]$$

where in this equation ε_L and ε_R denote, respectively, the extinction coefficients for left and right circularly polarized light.

The time dependence of the intensity of emitted light of polarization σ , at a particular wavelength, λ , for a specific transition $n \rightarrow g$ of a molecule with orientation Ω (in the laboratory frame) may be expressed in terms of the transition probability, W_{gn}^σ as follows:

$$I_\sigma = (\lambda, t) = \left(\frac{hc}{\lambda} \right) N_n(\Omega, t) W_{gn}^\sigma(\Omega) f_\sigma(\lambda) \quad [4]$$

where $N_n(\Omega, t)$ denotes the number of molecules in the emitting state $|n\rangle$ with orientation Ω at time t , and $f_\sigma(\lambda)$ is a normalized lineshape function. The number of

molecules in the emitting state with orientation Ω depends on the orientation at the time of excitation ($t=0$) with respect to the polarization π and direction of the exciting beam.

$$N_n(\Omega, t) = N_e^\pi(\Omega; \Omega_0, t) \eta_n \quad [5]$$

η_n denotes the fraction of molecules that end up in state $|n\rangle$ that were initially prepared in the intermediate state $|e\rangle$ by the excitation beam. This quantity is assumed to be independent of orientation. In the most general case it is required to describe the time dependence of any conformational changes that take place between the time of excitation and emission, but for simplicity this will not be considered in the treatment presented here. The differential intensity of left minus right circularly polarized light may now be expressed as follows:

$$\Delta I(\lambda, t) = \left(\frac{hc}{\lambda}\right) N_n(\Omega, t) \Delta W_{gn}(\Omega) f(\lambda) \quad [6]$$

where the differential transition probability ΔW_{gn} has been introduced

$$\Delta W_{gn}(\Omega) = W_{gn}^L(\Omega) - W_{gn}^R(\Omega) \quad [7]$$

The probability of emitting a right or left circularly polarized photon may be related in the usual way to molecular transition matrix elements through Fermi's Golden Rule. Under the assumption that the emitted light is being detected in the laboratory 3 direction (see **Figure 1**), and allowing for electric and magnetic dipoles in the expansion of the molecule-radiation interaction

Hamiltonian, one obtains the following expressions:

$$W_{gn}^L(\Omega) = K(\lambda^3) \left[|\mu_1^{gn}|^2 + |\mu_2^{gn}|^2 + |m_1^{gn}|^2 + |m_2^{gn}|^2 - 2i(\mu_1^{gn} m_1^{gn} + \mu_2^{gn} m_2^{gn}) \right] \quad [8]$$

$$W_{gn}^R(\Omega) = K(\lambda^3) \left[|\mu_1^{gn}|^2 + |\mu_2^{gn}|^2 + |m_1^{gn}|^2 + |m_2^{gn}|^2 + 2i(\mu_1^{gn} m_1^{gn} + \mu_2^{gn} m_2^{gn}) \right] \quad [9]$$

where $K(\lambda^3)$ is a proportionality constant, 1 and 2 refer to laboratory axes and the electric dipole transition moment μ^{gn} and the imaginary magnetic dipole transition moment m^{gn} are defined as follows:

$$\begin{aligned} \mu_1^{gn} &\equiv \langle g | \mu_1 | n \rangle \\ m_1^{gn} &\equiv \langle g | m_1 | n \rangle \end{aligned} \quad [10]$$

The differential transition rate is, therefore,

$$\Delta W_{gn}(\Omega) = K(\lambda^3) [2i(\mu_1^{gn} m_1^{gn} + \mu_2^{gn} m_2^{gn})] \quad [11]$$

The final connection between molecular properties and experimental observables requires knowledge of the orientational distribution of the emitting molecules with respect to the direction and polarization of the excitation light and the direction of detection and the time dependence of this distribution.

Circularly Polarized Luminescence from Solutions

There have been very few attempts at measuring CPL from oriented samples due to the inherent problems

Figure 1 Laboratory (1,2,3) and molecular (x,y,z) coordinate systems, and the Euler rotation matrix, ($\bar{R}$).

associated with measurement of circular polarization in the presence of linear polarization. For this reason the discussion of the orientation dependence of CPL to randomly oriented molecular samples such as in liquid solutions is restricted. Of course, even if the ground state distribution is randomly oriented (isotropic), the emitting state may not be, due to the photoselection of the emitting sample by the excitation beam. An orientational distribution is represented by brackets $\langle \rangle$. Substitution of eqns [5] and [11] into eqn [6], and allowing for an ensemble of orientations one obtains the following:

$$\Delta I(\lambda, t) = \left(\frac{2ibc\eta_n}{\lambda} \right) K(\lambda^3) \langle N_e^\pi(\Omega: \Omega_0, t) \times [\mu_1^{eg} m_1^{gn} + \mu_2^{gn} m_2^{gn}] \rangle f(\lambda) \quad [12]$$

The time dependence of the orientational distribution, $\eta(\Omega, t)$, may be formally separated from the number of molecules excited at time $t=0$ by an excitation pulse as follows:

$$N_e^\pi(\Omega: \Omega_0, t) = N_e^\pi(\Omega_0) \eta(\Omega, t) \quad [13]$$

$N_e^\pi(\Omega_0)$ may be calculated from knowledge of the initial distribution, and direction and polarization of the excitation beam.

$$N_e^\pi(\Omega_0) = \kappa^2 |\mu^{eg} \cdot \pi|^2 \quad [14]$$

where μ^{eg} is the absorption transition vector and κ is a proportionality constant. Final expressions for the formal relationship between the time-dependent CPL intensity or g_{um} require knowledge of experimental geometry, and $\eta(\Omega, t)$.

For purposes of illustration, one examines here the most common situation of random (isotropic) ground state distributions and 90° excitation/emission geometry with unpolarized excitation. If the emission is detected in the laboratory 3 direction, then the excitation is polarized in the 13 plane. Eqn [13] may then be written as

$$N_e^\pi(\Omega_0) = \kappa^2 [|\mu_1^{eg}|^2 + |\mu_3^{eg}|^2] \quad [15]$$

and the final formal expression (in the laboratory coordinate system) is obtained by substituting this result into eqn [12]:

$$\Delta I(\lambda, t) = \left(\frac{2ibc\eta_n \kappa^2}{\lambda} \right) K(\lambda^3) \left\langle [|\mu_1^{eg}|^2 + |\mu_3^{eg}|^2] [\mu_1^{gn} m_1^{gn} + \mu_2^{gn} m_2^{gn}] \right\rangle \eta(\Omega, t) f(\lambda) \quad [16]$$

where the square brackets are explicitly labelled to indicate that the absorption takes place at time 0 and the emission at time t .

The ensemble average over molecular orientations implied in eqn [16] may be performed if $\eta(\Omega, t)$ is known. First consider the case in which the emitting sample is 'frozen', that is the orientational distribution of emitting molecules is identical to that prepared by the excitation beam. In this case $\eta(\Omega, t) = \exp(-t/\tau)$, where τ denotes the emission lifetime, and, since the orientations are fixed, the subscripts on the square brackets may be eliminated. The orientational average may be performed by relating the transition moments in the molecular coordinate system to the laboratory system using the appropriate elements of the Euler matrix (see **Figure 1**). If one assumes, for example, that the absorption transition moment defines the molecular z -axis, then one must evaluate terms such as the following:

$$\begin{aligned} & \langle |\mu_1^{eg}|^2 \mu_1^{gn} m_1^{gn} \rangle \\ &= \int_0^{2\pi} \int_0^{2\pi} \int_0^\pi |R_{1z}|^2 R_{1z} R_{1z} d\theta d\psi d\phi |\mu_z^{eg}|^2 \mu_z^{gn} m_z^{gn} \end{aligned} \quad [17]$$

This photoselection of emitting distributions also affects the measurement of total luminescence, and the development of the formal expression for $I(t)$ parallels that presented earlier. The final result for $g_{\text{um}}(t)$ is obtained by evaluating all of the integrals implied in eqn [16], and the related expression for $I(t)$. In this particular simple model, the time-dependence is only in the decay of the emitting state, and is identical for ΔI and I , so that g_{um} is time independent. This resulting general expression for the 'frozen' limit is

$$g_{\text{um}}(\lambda) = 4i \frac{f_{\text{CPL}}(\lambda)}{f_{\text{TL}}(\lambda)} \left[\frac{7\mu_x^{gn} m_x^{gn} + 7\mu_y^{gn} m_y^{gn} + 6\mu_z^{gn} m_z^{gn}}{7|\mu_x^{gn}|^2 + 7|\mu_y^{gn}|^2 + 6|\mu_z^{gn}|^2} \right] \quad [18]$$

where different lineshapes for CPL and TL have been allowed and an arbitrary absorption transition direction. This result simplifies under conditions in which the absorption and emission transition directions are parallel. Furthermore, the reader is referred to the Further reading section concerning the results expected for other excitation/emission geometries. It should be noted that if the luminescence is partially linearly polarized, the measurement of CPL is problematic due to experimental artifacts. For this reason it is usually the case that the excitation/emission geometry and incident polarization are chosen so as to eliminate the possibility of linear polarization in the luminescence.

The other useful limiting case is the situation in which the orientation of emitting molecules is isotropic (random). This limiting case is appropriate for small molecular systems with relatively long emission lifetimes. If the distribution prepared by the excitation beam has been completely randomized by the time of emission,

then eqn [16] reduces to:

$$\Delta I(\lambda, t) = \left(\frac{2ibc\eta_n\kappa^2}{\lambda} \right) K(\lambda^3) \langle \mu_1^{gn} m_1^{gn} + \mu_2^{gn} m_2^{gn} \eta(\Omega, t) \rangle f(\lambda) \quad [19]$$

where the absorption strength and other parameters associated with the excitation into the constants have been assimilated. The orientational averaging in this equation involves the product of only two elements of the Euler matrix. Just as in the previous discussion, the time dependence of the total luminescence and the CPL for this model are identical. The final formal relationship for this 'isotropic' limit is

$$g_{\text{lum}}(\lambda) = 4i \frac{f_{\text{CPL}}(\lambda)}{f_{\text{TL}}(\lambda)} \left[\frac{\mu^{gn} \cdot m^{gn}}{|\mu^{gn}|^2} \right] \quad [20]$$

The major difference between this result and the frozen result is the fact that, in eqn [18], the different components of the emission transition vectors contribute unequally to the observable. In principle, this would allow one to investigate the chirality of molecular transitions along specific molecular directions, but this has not been exploited.

Equation [20] illustrates one of the operational principles of CPL (and CD) spectroscopy. In most situations one is interested in studying transitions that are formally forbidden. If the transition is allowed, the dipole strength, which is proportional to the denominator of eqn [20], is large. Since the rotatory strength represented by the numerator of eqn [20] is generally quite small, because of the magnitude of the magnetic dipole transition moment, g_{lum} (or g_{abs}) for allowed transitions is usually very small. In CPL spectroscopy this leads to the practical result that one does not generally study highly luminescent dyes, or other strongly allowed transitions, but rather, the most interesting molecular structural information comes from the study of weakly or mildly luminescent transitions in which the inherent molecular chirality is closely connected with the emissive chromophore.

Circularly Polarized Luminescence from Racemic Mixtures

One of the most useful applications of CPL spectroscopy has been in the study of racemic mixtures. This experiment is possible, because, even though the ground state is racemic, the emitting state can sometimes be photo-prepared in an enantiomerically enriched state by use of circularly polarized excitation. If the racemization rate of the excited state is less than the emission rate, then the emission will be circularly polarized. A racemic sample containing equal concentrations of R and S enantiomers is considered. The preferential absorption of circularly

polarized light is related to the CD through the absorption dissymmetry ratio g_{abs} which was defined in eqn [3]. Rewriting this equation for the CD of the R enantiomer one obtains the following:

$$g_{\text{abs}}^R = \frac{\Delta\epsilon}{\epsilon} = \frac{\epsilon_L(R) - \epsilon_R(R)}{\frac{1}{2}(\epsilon_L(R) + \epsilon_R(R))} \quad [21]$$

The number of R enantiomers that absorb left circularly polarized light, $N_L(R)$ is proportional to $\epsilon_L(R)$, and similarly for $\epsilon_R(R)$. Thus, one may make the following substitution:

$$g_{\text{abs}}^R = \frac{N_L(R) - N_R(R)}{\frac{1}{2}(N_L(R) + N_R(R))} \quad [22]$$

since all of the proportionality constants cancel. The number of R enantiomers that would absorb right circularly polarized light is exactly equal to the number of S enantiomers that would absorb left circularly polarized light, that is $N_R(R) = N_L(S)$. This substitution yields the following:

$$g_{\text{abs}}^R = \frac{N_L(R) - N_L(S)}{\frac{1}{2}(N_L(R) + N_L(S))} = \frac{2\Delta N_L}{N_L} \quad [23]$$

ΔN_L is the differential population ($R - S$) of excited enantiomers that would result from left circularly polarized excitation.

In general, an exact description of CPL from racemic mixtures requires consideration of the competition between racemization and emission. Under the assumption that racemization is much slower than emission, the following expression for CPL from a racemic mixture under left circularly polarized excitation may be written as follows:

$$g_{\text{lum}}^L(\lambda) = 4i \frac{f_{\text{CPL}}(\lambda)\Delta N_L}{f_{\text{TL}}(\lambda)N_L} \left[\frac{\mu^{gn}(R) \cdot m^{gn}(R)}{|\mu^{gn}(R)|^2} \right] \quad [24]$$

Substituting from above one obtains the following expression:

$$g_{\text{lum}}^L(\lambda) = \frac{1}{2} g_{\text{abs}}^R(\lambda') g_{\text{lum}}^R(\lambda) \quad [25]$$

where the excitation wavelength is explicitly labelled as λ' . Examination of eqn [25] shows that the measurement of CPL from racemic mixtures depends on the product of the CD and CPL. Since the measurement of g_{lum} is generally limited to magnitudes greater than 10^{-4} , the magnitude of the intrinsic dissymmetry ratios must usually be greater than 10^{-2} for this unique measurement to be feasible. This restriction has limited applications of this technique to racemic lanthanide complexes, since intraconfigurational $f \leftrightarrow f$ transitions that obey magnetic

dipole transition rules (i.e. $\Delta J=0, \pm 1$) often are associated with dissymmetry ratios greater than 0.1.

Time-Resolved Circularly Polarized Luminescence

For the simple model enantiopure systems described earlier, it was concluded that the time dependence of the CPL and total luminescence were identical, and, therefore, the dissymmetry ratio contained no dynamic molecular information. This, of course, would not be the case if intramolecular geometry changes, that would affect the chirality of the molecular transitions, were occurring on the same time scale as emission. Time-resolved CPL measurements have been useful in the study of racemic mixtures of lanthanide complexes in which racemization or excited state quenching is occurring on the same time scale as emission.

It was assumed in the previous section that the enantiomer-enriched excited state population, which was prepared from a racemic ground state distribution by a circularly polarized excitation beam, was maintained until the time of emission. If this is not the case, then the differential excited state population is time-dependent. Neglecting orientational effects, the following expression for the time-dependence of the excited state population following an excitation pulse of left circularly polarized light may be derived

$$\Delta N^L(t) = \Delta N^L(0) \exp(-2k_{\text{rac}}t - k_0t) \quad [26]$$

where k_{rac} is the racemization rate and k_0 is the excited state decay rate. Since the total number of emitting molecules decays as

$$N^L(t) = N^L(0) \exp(-k_0t) \quad [27]$$

one can express the time-dependence of the luminescence dissymmetry as follows:

$$g_{\text{lum}}^L(t) = g_{\text{lum}}^L(0) \exp(-2k_{\text{rac}}t) \quad [28]$$

This technique has been used in a number of studies in which the decay of g_{lum} has been analysed to extract the racemization rate constant.

It is also possible to extract dynamic information concerning racemization rates through measurement of steady-state CPL. Again neglecting time-dependent orientational effects, one may integrate eqns [26] and [27] over long times ($0 \rightarrow \infty$) and obtain the following result:

$$g_{\text{lum}}^L(\lambda) = \frac{1}{2} g_{\text{abs}}^R(\lambda') g_{\text{lum}}^R(\lambda) \left(\frac{k_0}{2k_{\text{rac}} + k_0} \right) \quad [29]$$

This equation has the expected limiting behaviour. If $k_{\text{rac}} \ll k_0$ then the result of eqn [25] is obtained, and if $k_{\text{rac}} \gg k_0$ then the magnitude of g_{lum} becomes negligibly small.

The second application of time-resolved CPL is in the study of enantioselective (or more properly, diastereomer-selective) quenching. In these experiments an enantiopure quencher molecule is added to a racemic solution. The interaction of the chiral quencher with the individual enantiomers is such that the excited state of one of the enantiomers is quenched more rapidly than the other. This process is depicted schematically in **Figure 2**, where it is assumed that the quencher is an R enantiomer, and k_{RS} and k_{RR} denote the quenching rate constants. This process may be described using the following simple kinetic model:

These reactions are modelled in terms of a diffusional step (k_{diff}^- or k_{diff}^+), resulting in the formation of a bimolecular encounter complex. This is followed by competing pathways for dissociation of the complex (k_{diff}^- or k_{diff}^+) or energy transfer (k_{ET}^- or k_{ET}^+). Deactivation of the excited quencher is described by k_p . The observed CPL is directly proportional to the difference in excited state concentrations of the two enantiomers, and this may be related to the specific rate constants introduced above. Assuming that the diffusion and deactivation are independent of chirality, one can derive the following expression for $\Delta N(t)$:

$$\Delta N(t) = [S^*](t) - [R^*](t) = [S]_0 e^{-k_{\text{RS}}^{\text{obs}} t} - [R]_0 e^{-k_{\text{RR}}^{\text{obs}} t} \quad [32]$$

Figure 2 Schematic energy level diagram for measurement of CPL from a racemic mixture.

where

$$\begin{aligned}k_{\text{obs}}^{\text{RS}} &= k_{\text{RS}}[S] + k_0 \\ k_{\text{obs}}^{\text{RR}} &= k_{\text{RR}}[R] + k_0\end{aligned}\quad [33]$$

and

$$\begin{aligned}k_{\text{RR}} &= \frac{k_{\text{ET}}^+ k_{\text{diff}}}{k_{\text{ET}}^+ + k_{\text{diff}}^+} \\ k_{\text{RS}} &= \frac{k_{\text{ET}}^- k_{\text{diff}}}{k_{\text{ET}}^- + k_{\text{diff}}^-}\end{aligned}\quad [34]$$

If the quenching reactions are far from diffusion control (i.e. $k_{\text{ET}} \ll k_{\text{diff}}$), then one can express the diastereomeric quenching rate constants in terms of equilibrium constants for formation of the diastereomeric ion pairs.

$$\begin{aligned}k_{\text{RR}} &= K^+ k_{\text{ET}}^+ \\ k_{\text{RS}} &= K^- k_{\text{ET}}^-\end{aligned}\quad [35]$$

Thus, the time-dependence of $\Delta I(t)$ or $g_{\text{lum}}(t)$ may be used as a probe of the fundamental differences in the interaction of chiral molecules.

Spectra–Structure Correlations

The theoretical discussion presented above has focused on developing formal relationships between the molecular transition integrals and the experimental observables. These are, of course, of primary importance in interpreting CPL measurements in terms of inter- and intramolecular processes, including molecular reorientation,

racemization and chemical reactions which affect the net molecular chirality. These processes are all well understood, and specific information is most often obtained within an appropriate model system. The more fundamental aspects of molecular chirality associated with the molecular transition matrix elements is less well developed. Although there have been a few successes in interpreting the sign and magnitude of a CPL spectrum in terms of the identity and structure of a specific enantiomer, in this regard, it is certainly not the case that the technique is as well developed as CD spectroscopy. Even in the case of fairly highly symmetric chiral lanthanide complexes, the level of computation and development of f-f intensity theory is not yet at the stage where one can associate *a priori* the sign of an individual transition with the identity of the enantiomer in all cases.

Symbols

c	velocity of light
c	concentration in mol l ⁻¹
d	optical pathlength
D^{NnKk}	dipole strength for the transition $ Nn\rangle \rightarrow Kk\rangle$
D_{ij}^{NnKk}	transition moment tensor for the transition $ Nn\rangle \rightarrow Kk\rangle$
$-e$	charge of the electron
E_n	energy of the state $ n\rangle$
f	orientational distribution function
F^{NK}	factor taking into account a change of intensity of the monomer bands
F^{NnKk}	spectral function for the absorption band of the transition $ Nn\rangle \rightarrow Kk\rangle$
g	dissymmetry factor
G^{NnKk}	spectral function of the vibronic transition $ Nn\rangle \rightarrow Kk\rangle$
$h, \hbar = h/2\pi$	Planck's constant
l_i	ligand
$\langle m_r \rangle_{n0}$	coordinate of the magnetic dipole transition moment for the transition $ 0\rangle \rightarrow n\rangle$
m	mass of the electron
$\langle \vec{m}_{ia0} \rangle$	magnetic dipole transition moment of group i for the transition $ 0\rangle \rightarrow a\rangle$
$\langle \vec{m} \rangle_{NnKk}$	magnetic dipole transition moment for the transition $ Nn\rangle \rightarrow Kk\rangle$
M_{ij}	optical rotation tensor
$[M]$	molar rotation
n, k	vibrational states
$n_{1,2, L,R}$	refractive indices for linearly or circularly polarized light
N	number of molecules in a volume V
N_A	Avogadro's number
N, K	electronic states
p_i	operator of the linear momentum
$\langle Q_{sj} \rangle_{n0}$	electric quadrupole transition moment for the transition $ 0\rangle \rightarrow n\rangle$
R	degree of anisotropy
R^{0A}	rotational strength for the transition $ 0\rangle \rightarrow A\rangle$
R^{NnKk}	rotational strength for the electronic transition $ Nn\rangle \rightarrow Kk\rangle$

$\langle \vec{R}_i \rangle$	distance vector of group i from the origin of the coordinate system
$\vec{R}_{ij}$	distance vector between two groups i, j
R_{ij}^{NnKk}	rotational strength tensor for the transition $ Nn\rangle \rightarrow Kk\rangle$
$V_{irs, jtv}$	interaction potential between groups i, j
V	potential of the perturbing atoms
$\hat{V}_{ij}$	potential energy operator
$2V_{ij}$	Davidov splitting
x_b, x'_i	axes of the molecule fixed or space fixed coordinate system
α, β, γ	Eulerian angles
δ_{ij}	Kronecker symbol
$\Delta\epsilon$	CD of an isotropic system
$\Delta\epsilon_{ii} (i=1,2,3)$	coordinates of the CD tensor
$\Delta\epsilon_{ij}$	circular dichroism tensor
ϵ_{ij}	absorption tensor
ϵ_{ijk}	Levi Civita tensor
ϵ	molar decadic absorption coefficient
$\epsilon_{1,2,L,R}$	absorption coefficients for linearly or circularly polarized light
η	positive damping parameter representing the natural line shape
θ	ellipticity
$\theta_{LB,CD}$	ellipticity related to linear birefringence or circular dichroism
ϑ	angle between the electric dipole transition moments of two fragments
λ	wavelength
$\lambda_{Nn}, \lambda_{Kk}$	librational states
$\lambda(l_i), \mu(l_i)$	phenomenological parameters for ligand l_i
$\langle \mu_r \rangle_{0n}$	coordinate of the electric dipole transition moment for the transition $ 0\rangle \rightarrow n\rangle$
$\langle \vec{\mu} \rangle_{NnKk}$	electric dipole transition moment for the transition $ Nn\rangle \rightarrow Kk\rangle$
$\langle \vec{\mu} \rangle_{iaa}$	electric dipole transition moment of group i for the transition $ 0\rangle \rightarrow a\rangle$
$\bar{\nu}$	wavenumber
$\bar{\nu}_x$	wavenumber for the $(k^{\text{th}} + 1)$ band of a progression

$\bar{\nu}_{00}$	wavenumber for the origin of a progression
$\bar{\nu}_0$	centre of the exciton bands
ϕ	optical rotation
$\phi_{LD,CB}$	rotation related to linear dichroism or circular birefringence
$\hat{\phi}$	complex optical rotation
φ_{ij}	group wave functions
$\chi(l_1, l_2, l_3, l_4)$	chirality function
$\omega = 2\pi c\bar{\nu}$	frequency

Introduction and Molecular Description of Absorption and Circular Dichroism

The interaction of light with an oriented molecule or an ensemble of oriented molecules can be treated as a scattering process with photons or semiclassically as an induction process of electric or magnetic moments by an electromagnetic field. As a result of this interaction the incident light beam undergoes changes in its state of polarization and its intensity. Using Gō's description, the complex optical rotation $\hat{\phi}$ can be given as a sum of the contributions of individual molecules:

$$\begin{aligned}\hat{\phi} &= \phi + i\theta \\ &= \frac{Nd}{8\pi^2 V} \int f(\alpha, \beta, \gamma) H'_{21}(\alpha, \beta, \gamma) \sin \beta \, d\alpha d\beta d\gamma \quad [1]\end{aligned}$$

with

$$\begin{aligned}H'_{21} &= -\frac{2\pi i e^2}{\hbar m^2 c \omega} \\ &\times \sum_n \left\{ \frac{\langle p'_2 \exp(-ikx'_3) \rangle_{0n} \langle p'_1 \exp(ikx'_3) \rangle_{n0}}{\omega_{n0} - \omega - i\eta} \right. \\ &\quad \left. + \frac{\langle p'_1 \exp(ikx'_3) \rangle_{0n} \langle p'_2 \exp(-ikx'_3) \rangle_{n0}}{\omega_{n0} + \omega + i\eta} \right\} \quad [2]\end{aligned}$$

and

$$\begin{aligned}\langle p'_j \exp(\pm ikx'_3) \rangle_{nm} &= \langle n | \sum_{\mu} p'_{j\mu} \exp(\pm ikx'_{3\mu}) | m \rangle \\ j &= 1, 2 \quad [3]\end{aligned}$$

Here $f(\alpha, \beta, \gamma)$ is the orientational distribution function of an ensemble of molecules, which is normalized by $1/8\pi^2 \int f(\alpha, \beta, \gamma) \sin \beta d\alpha d\beta d\gamma = 1$, where α, β, γ are the Eulerian angles, N denotes the number of molecules in the volume V , d is the optical pathlength, Σ_{μ} represents the sum over all electrons of a molecule, m and $-e$ are the mass and the charge of the electron, p'_j is the operator of the linear momentum, $\omega = 2\pi c\bar{\nu}$, c is the velocity of light in a vacuum, $k = \omega/c$, η is a positive damping parameter representing the natural line shape,

$\omega_{n0} = 2\pi c\bar{\nu}_{n0} = \hbar^{-1}(E_n - E_0)$, and E_n and E_0 are the energies of the states $|n\rangle$ and $|0\rangle$. Primed symbols refer to the space-fixed coordinate system and unprimed letters to the molecule-fixed coordinate system. ϕ is the optical rotation and θ represents the ellipticity of the light beam emerging from the sample. H'_{21} is an element of the interaction matrix H'_{ij} of a photon and an atom or an oriented molecule. The incident light is propagating in the x'_3 direction and is polarized in the $x'_1x'_2$ plane. Using the relation

$$\begin{aligned}\langle p'_2 \exp(-ikx'_3) \rangle_{0n} \langle p'_1 \exp(ikx'_3) \rangle_{n0} \\ = \langle p'_1 \exp(ikx'_3) \rangle_{0n} \langle p'_2 \exp(-ikx'_3) \rangle_{n0} \quad [4]\end{aligned}$$

where the wave functions $|j\rangle$ are chosen to be real. Expanding the exponentials of eqn [2] into a series which converges very rapidly if the extension of the molecule is small compared to the wavelength of the incident light, it follows that the complex optical rotation is given by

$$\begin{aligned}\hat{\phi} &= -\frac{iNd}{2\pi\hbar cV} \int f(\alpha, \beta, \gamma) \sin \beta \, d\alpha d\beta d\gamma \\ &\times \left\{ \sum_n \frac{\omega}{\omega_{n0}^2 - \omega^2 - 2i\eta\omega} [\omega_{n0} D'^{0n}_{12}(\alpha, \beta, \gamma) \right. \\ &\quad \left. + 2i\omega R'^{0n}_{123}(\alpha, \beta, \gamma)] \right\} \quad [5]\end{aligned}$$

where D'^{0n}_{12} is a coordinate of the transition moment tensor. Loxsom has discussed the effect of an increasing extension-to-wavelength ratio. The third rank tensor R'^{0n}_{123} , antisymmetric with respect to the first two indices, can be replaced by a symmetric pseudotensor R'^{0n}_{ij} of rank two which is called the tensor of rotation. This tensor of rotation can be decomposed into a magnetic dipole and an electric quadrupole contribution

$$R'^{0n}_{ij} = \frac{1}{4} \sum_{r,s} \langle \mu_r \rangle_{0n} (\varepsilon_{rsi} \langle C_{sj} \rangle_{n0} + \varepsilon_{rsj} \langle C_{si} \rangle_{n0}) \quad [6]$$

with

$$\langle C_{sj} \rangle_{n0} = -i \sum_r \varepsilon_{sjr} \langle m_r \rangle_{n0} - \frac{\omega_{n0}}{c} \langle Q_{sj} \rangle_{n0} \quad [7]$$

and

$$\begin{aligned}\mu_i &= -e \sum_v x_{iv} \quad Q_{ij} = -\frac{1}{2} e \sum_v x_{iv} x_{jv} \\ m_r &= -\frac{e}{2mc} \sum_v \sum_{i,j} \varepsilon_{rij} x_{iv} p_{jv} \quad [8]\end{aligned}$$

Here, $\langle \mu_i \rangle_{0n}$ and $\langle m_i \rangle_{n0}$ represent the coordinates of the electric and magnetic dipole transition moment vectors, respectively, $\langle Q_{ij} \rangle_{n0}$ is a coordinate of the electric quadrupole transition moment tensor, and ε_{ijk} is

the Levi–Civita tensor. Operators depending on the dynamic variables of the nuclei are omitted because they do not contribute to the effect in the approximation used.

The complex optical rotation $\hat{\phi}$ contains the elliptical birefringence and dichroism, which can be given for small effects as a superposition of a linear and a circular birefringence and dichroism:

$$\hat{\phi} = \phi_{LD} + \phi_{CB} + i[\theta_{LB} + \theta_{CD}] \quad [9]$$

with the linear birefringence (LB) and dichroism (LD) effects

$$\theta_{LB} = -\pi \bar{v} d (n_1 - n_2) \quad \phi_{LD} = \frac{1}{4} (\ln 10) (\varepsilon_1 - \varepsilon_2) c d \quad [10]$$

and the circular birefringence (CB) and dichroism (CD) effects

$$\phi_{CB} = \pi \bar{v} d (n_L - n_R), \quad \theta_{CD} = \frac{1}{4} (\ln 10) (\varepsilon_L - \varepsilon_R) c d \quad [11]$$

Here ε_1 , ε_2 and n_1 , n_2 are the molar decadic absorption coefficients and the refractive indices for a linearly polarized light beam with a polarization parallel and perpendicular to the optical axis of a uniaxial sample, and ε_L , ε_R and n_L , n_R are the absorption coefficients and the refractive indices for the left and right circularly polarized light beams, respectively. In the approximation used the CD/CB and LD/LB effects are additive. From the theory of the Cauchy–Rieman differential equations it can be shown that the Kramers–Kronig transforms derived with microcausality as the only presupposition are also valid for a system of oriented molecules:

$$\theta_{LB}(\omega) = -\frac{2}{\pi} \oint \frac{\bar{\omega} \phi_{LD}(\bar{\omega})}{\bar{\omega}^2 - \omega^2} d\bar{\omega} \quad [12]$$

$$\theta_{CB}(\omega) = \frac{2}{\pi} \oint \frac{\omega \theta_{CD}(\bar{\omega})}{\bar{\omega}^2 - \omega^2} d\bar{\omega} \quad [13]$$

The frequency dependence given in eqns [2] and [5] is based on a situation where a natural line width is found. In all cases where optical activity has been analysed, for example in a gas or in a liquid or solid phase, the bandwidth is determined by the broadening of rotational states – for which the theory of optical activity is not well developed and no experimental analysis exists – or by the existence of librational states etc. Therefore, broadened rotational states or librational states can be introduced for which the spectrum can be considered as a quasi-continuum. With the assumption of the Born–Oppenheimer approximation, the states $|0\rangle$ and $|n\rangle$ can then be given as a product of vibronic states and librational states λ_{Nn} and λ_{Kk} as follows

$$|0\rangle = |Nn\rangle |\lambda_{Nn}(\omega)\rangle \quad \text{and} \quad |n\rangle = |Kk\rangle |\lambda_{Kk}(\omega)\rangle \quad [14]$$

where $|Nn\rangle$ and $|Kk\rangle$ represent the vibronic electronic ground and excited states, respectively. n and k are quantum numbers for the vibrational states in the electronic states N and K , respectively. An integration over the quasi-continuum of the librational states ω and the neglect of the natural bandwidth η yields the spectral functions $F^{NnKk}(\bar{v})$ and $G^{NnKk}(\bar{v})$ for the absorption and the circular dichroism effect which are equal for most of the experimental conditions given. With the new line shape of the absorption band $F^{NnKk}(\bar{v})$ and the circular dichroism $G^{NnKk}(\bar{v})$, the coordinates of the absorption ε_{ij} (eqn [15]) and circular dichroism tensor $\Delta\varepsilon_{ij}$ (eqn [16]) are given by

$$\varepsilon_{ij}(\bar{v}) = \frac{B\bar{v}}{4} \sum_n \sum_{Kk} D_{ij}^{NnKk} F^{NnKk}(\bar{v}) \quad [15]$$

and

$$\Delta\varepsilon_{ij}(\bar{v}) = B\bar{v} \sum_n \sum_{Kk} R_{ij}^{NnKk} G^{NnKk}(\bar{v}) \quad [16]$$

where for the vibronic transition $|Nn\rangle \rightarrow |Kk\rangle$, the dipole transition moment tensor is defined by

$$D_{ij}^{NnKk} = \langle \mu_i \rangle_{NnKk} \langle \mu_j \rangle_{KkNn} \quad [17]$$

and the rotational strength tensor R_{ij}^{NnKk} is given analogously to the rotational strength tensor in eqns [6] and [7] by replacing $|0\rangle \rightarrow |n\rangle$ with $|Nn\rangle \rightarrow |Kk\rangle$ and

$$B = \frac{32\pi^3 N_A}{10^3 b c \ln 10} = 7.653 \times 10^{40} \text{ cgs} \quad [18]$$

N_A is the Avogadro's number, c the velocity of light and b the Planck's constant. Together with the Kramers–Kronig transforms (eqns [12] and [13]), the frequency dependence of the optical rotation tensor can be obtained as follows

$$M_{ii}(\bar{v}) = \frac{288\pi N_A \bar{v}}{b c} \sum_n \sum_{Kk} R_{ii}^{NnKk} J_2^{NnKk}(\bar{v}) \quad [19]$$

$$J_2^{NnKk}(\bar{v}) = \oint \frac{\bar{v} G^{NnKk}(\bar{v}) d\bar{v}'}{\bar{v}'^2 - \bar{v}^2} \quad [20]$$

$J_2^{NnKk}(\bar{v})$ in eqn [19] is the principal value of the integral over the singularity in the wavenumber region of an absorption process.

Absorption and Circular Dichroism in Isotropic Media

For isotropic solutions, the orientational distribution function $f(\alpha, \beta, \gamma)$ in eqn [5] is equal to one and the absorption coefficient $\varepsilon(\bar{v})$, the circular dichroism $\Delta\varepsilon(\bar{v})$, and the molar optical rotation $[M(\bar{v})]$ (optical rotatory

dispersion – ORD) are one-third of the trace of the corresponding tensor or pseudotensor of the second rank, respectively,

$$\begin{aligned}\varepsilon(\bar{\nu}) &= \frac{1}{3} \sum_i \varepsilon_{ii} = \frac{B\bar{\nu}}{12} \sum_n \sum_{kk} D^{NnKk} F^{NnKk}(\bar{\nu}) \\ &= \sum_K \varepsilon^{NK}(\bar{\nu})\end{aligned}\quad [21]$$

with the dipole strength of the transition $|Nn\rangle \rightarrow |Kk\rangle$

$$\begin{aligned}D^{NnKk} &= \sum_i D_{ii}^{NnKk} \\ &= \sum_i \langle \mu_i \rangle_{NnKk} \langle \mu_i \rangle_{KkNn} = \langle \vec{\mu} \rangle_{NnKk}^2\end{aligned}\quad [22]$$

and

$$\begin{aligned}\Delta\varepsilon(\bar{\nu}) &= \frac{1}{3} \sum_i \Delta\varepsilon_{ii} = \frac{B\bar{\nu}}{3} \sum_n \sum_{kk} R^{NnKk} F^{NnKk}(\bar{\nu}) \\ &= \sum_K \Delta\varepsilon^{NK}(\bar{\nu})\end{aligned}\quad [23]$$

with the rotational strength R^{NnKk} of the transition $|Nn\rangle \rightarrow |Kk\rangle$ derived from the rotational strength tensor

$$\begin{aligned}R_{ij}^{NnKk} &= -\frac{1}{2}i \sum_{r,l} \langle \mu_r \rangle_{NnKk} \cdot \langle m_l \rangle_{KkNn} \\ &\quad \times \left[\delta_{ri} \delta_{lj} - \frac{1}{2} \delta_{ri} \cdot \delta_{lj} - \frac{1}{2} \delta_{rj} \cdot \delta_{li} \right] \\ &\quad - \frac{\omega_{KkNn}}{4c} \sum_{r,s} \langle \mu_r \rangle_{NnKk} [\varepsilon_{rsi} \langle Q_{sj} \rangle_{KkNn} \\ &\quad + \varepsilon_{rsj} \langle Q_{si} \rangle_{KkNn}]\end{aligned}\quad [24]$$

where δ_{ij} is the Kronecker symbol. The contribution of the electric quadrupole transition moments cancels in the isotropic solution. Then a scalar product of the electric and magnetic dipole transition moments follows for the rotational strength

$$\begin{aligned}R^{NnKk} &= \sum_i R_{ii}^{NnKk} = \sum_i \text{Im} \{ \langle \mu_i \rangle_{NnKk} \langle m_i \rangle_{KkNn} \} \\ &= \text{Im} \{ \langle \vec{\mu} \rangle_{NnKk} \cdot \langle \vec{m} \rangle_{KkNn} \}\end{aligned}\quad [25]$$

The ORD is now given by

$$\begin{aligned}[M(\bar{\nu})] &= \frac{1}{3} \sum_i M_{ii} = \frac{288\pi N_A \bar{\nu}}{3bc} \sum_n \sum_{kk} R^{NnKk} J_2^{NnKk}(\bar{\nu}) \\ &= \sum_K [M^{NK}(\bar{\nu})]\end{aligned}\quad [26]$$

If vibronic states n, k do not contribute to the ORD, there follows from eqn [26] with the dispersion

$$J_2^{NK}(\bar{\nu}) = \frac{\bar{\nu}^2}{\bar{\nu}_{NK}^2 - \bar{\nu}^2} \quad [27]$$

the well-known Rosenfeld equation.

The right sides of eqns [23] and [26] lead to an interpretation of the CD and ORD spectra as a sum of contributions of the electronic transitions. To every absorption band $\varepsilon^{NK}(\bar{\nu})$ belongs a $\Delta\varepsilon^{NK}(\bar{\nu})$ and a corresponding ORD curve $[M^{NK}(\bar{\nu})]$ as presented in **Figure 1**. It is evident from **Figure 1** that the optical rotation $[M^{NK}(\bar{\nu})]$ possesses a larger half bandwidth than $\Delta\varepsilon^{NK}(\bar{\nu})$. Thus $[M(\bar{\nu})]$ can only be measured as a sum of contributions of many transitions independent of the chosen wavelength even in the wavelength region far away from absorption bands. In contrast to this, it is often possible to measure the CD curve of only one or an overlap of CD curves of a few transitions. The smaller bandwidth of the CD bands is the basis for the answer to the often-discussed question of why a CD measurement has advantages over an ORD measurement. In principle, one can measure either the circular dichroism or the optical rotatory dispersion because one measurable quantity can be evaluated from the other with the Kramers–Kronig relations (eqns [12] and [13]) if the frequency region measured is sufficiently large. From the numerical point of view the calculation of an ORD curve from a CD curve is easier than vice versa because of the smaller half bandwidth of the CD curves.

The different absorption bands, to which the CD and ORD belong, can be classified by the symmetry of the molecular states involved especially by their polarization, that is their transition moment direction which is defined

Figure 1 UV ($\varepsilon(\bar{\nu})$, —), CD ($\Delta\varepsilon(\bar{\nu})$, ····), and ORD ($[M(\bar{\nu})]$, ---) spectra of a compound as a sum of contributions $\varepsilon^{NK}(\bar{\nu})$ (—), $\Delta\varepsilon^{NK}(\bar{\nu})$ (·····) and $[M^{NK}(\bar{\nu})]$ (---) of different transitions (chromophores) $|N\rangle \rightarrow |K\rangle$.

Figure 2 Dependence of the polarized absorption on the angle α between the transition moment direction along the C_2 axis of phenanthrene and the plane of polarization of the light. The transition moment direction is defined by a vector $\vec{\mu}_0$ parallel to the direction of maximum absorption. The light beam propagates perpendicular to the plane of the molecule.

by eqns [6], [8], and [17] and visualized in **Figure 2**. Experimentally the polarization can be determined by the linear dichroism (eqn [10]) measurement usually described in polarized spectroscopy in terms of the degree of anisotropy R as

$$R = \frac{\epsilon_1 - \epsilon_2}{\epsilon_1 + 2\epsilon_2} = \frac{\epsilon_1 - \epsilon_2}{3\epsilon} \quad [28]$$

Furthermore, the dissymmetry factor

$$g(\bar{\nu}) = \frac{\Delta\epsilon(\bar{\nu})}{\epsilon(\bar{\nu})} \quad [29]$$

contains information about the kind of the Cotton effect (CE) of a compound and is a hint whether an effect is measurable or not. Nowadays, the lowest limit for the sensitivity with commercial instruments is approximately 10^{-7} .

From the Kramers–Kronig transformation and from the quantum theoretical description, sum rules for the rotational strength analogous to the Kuhn–Reichert sum rule for the absorption can be derived. This means that, for the sum over the rotational strength of all transitions of the CD spectrum of a molecule, one obtains

$$\sum_{N,n,K,k} R^{NnKk} = 0 \quad [30]$$

From this result it follows that the CD and ORD values decrease when going to wavelengths longer than those of the microwave spectral region or to wavelengths shorter than those of the vacuum UV. This can be understood from the fact that the ratio of the extension of the molecules and the wavelengths is either very much smaller or larger than for the UV-visible spectral region.

Vibrational Progressions in the CD and UV-Visible Spectra of an Electronic Transition

From eqns [21] and [23] it also follows that the UV ($\epsilon^{NK}(\bar{\nu})$) and the CD ($\Delta\epsilon^{NK}(\bar{\nu})$) band are built up by a sum of different vibrational progressions

$$\epsilon^{NK}(\bar{\nu}) = \frac{B\bar{\nu}}{12} \sum_n \sum_k D^{NnKk} F^{NnKk}(\bar{\nu}) \quad [31]$$

and

$$\Delta\epsilon^{NK}(\bar{\nu}) = \frac{B\bar{\nu}}{3} \sum_n \sum_k R^{NnKk} F^{NnKk}(\bar{\nu}) \quad [32]$$

In **Figure 3**, a term scheme and the corresponding CD and UV spectra for an example where two progressions contribute to the UV visible and the CD spectrum are constructed. The vibrational progressions can contribute according to eqns [31] and [32] to the UV and CD spectra of an electronic transition with vibrations of different symmetry and thus with differently polarized bands and CD contributions of different sign. This is analogous to the electronic spectra of a molecule where transitions of different polarization, that is different transition moment directions, contribute to the spectra (eqn [21]). This can be proven experimentally by a frequency-dependent degree of anisotropy (eqn [28]). To eliminate the effect of the vibrational fine structure one has to integrate over the whole band of the electronic transition $|N\rangle \rightarrow |K\rangle$. The dipole strength D^{NK} and the rotational strength R^{NK} include information about the electronic transition from the electronic ground state N to the electronic excited state K and are of interest for the characterization of the transition

$$D^{NK} = \frac{12}{B} \int \frac{\epsilon^{NK}(\bar{\nu})}{\bar{\nu}} d\bar{\nu} \quad [33]$$

$$R^{NK} = \frac{3}{B} \int \frac{\Delta\epsilon^{NK}(\bar{\nu})}{\bar{\nu}} d\bar{\nu} \quad [34]$$

The dimension is given, as still often used even today, in cgs units. A frequency-independent dissymmetry factor g can also be defined with the help of the dipole strength and rotational strength of the electronic transition

$$g = \frac{4R^{NK}}{D^{NK}} \quad [35]$$

For an allowed electric and allowed magnetic transition $|N\rangle \rightarrow |K\rangle$, the Franck-Condon factor $\langle n|k\rangle$ can be introduced and the rotational strength (eqn [34]) is then

Figure 3 Term scheme for an absorption and the corresponding CD band with contributions of one allowed ($\bar{\nu} = \bar{\nu}_{00} + n\bar{\nu}_1$) and one forbidden ($\bar{\nu} = \bar{\nu}_{00} + \bar{\nu}_x + n\bar{\nu}_1$) vibrational progression. $\bar{\nu}_{00}$ is the 0–0 transition band. $\bar{\nu}_1$ and $\bar{\nu}_x$ are a totally symmetric and a non-totally symmetric vibration, respectively. $n = 1, 2$, etc.

given by

$$R^{NK} = \sum_k R^{NnkK} = \text{Im} \left\{ \langle \vec{\mu} \rangle_{NK} \cdot \langle \vec{m} \rangle_{KN} \right\} \sum_k |\langle n|k \rangle|^2$$

$$= \text{Im} \left\{ \langle \vec{\mu} \rangle_{NK} \cdot \langle \vec{m} \rangle_{KN} \right\} \quad [36]$$

$\langle \vec{\mu} \rangle_{NK}$ and $\langle \vec{m} \rangle_{KN}$ are the electric and magnetic transition moments for the 0–0 transition, respectively (a 0–0 transition means a transition where neither excited vibrational nor excited rotational states of the ground and excited electronic states are involved). Analogously, the dipole strength D^{NK} can be evaluated by

$$D^{NK} = \sum_k D^{NnkK} = \langle \vec{\mu} \rangle_{NK} \cdot \langle \vec{\mu} \rangle_{KN} \sum_k |\langle n|k \rangle|^2$$

$$= \langle \vec{\mu} \rangle_{NK} \cdot \langle \vec{\mu} \rangle_{KN} \quad [37]$$

For forbidden electronic transitions, intensity is stolen from other allowed electronic transitions and thus further terms have to be added in eqns [36] and [37] (Herzberg–Teller theory of vibronic coupling).

Classification of Absorption and Circular Dichroism Spectra and of Chromophores

Classifications of Absorption and CD Bands

Electronic transitions $|N\rangle \rightarrow |K\rangle$ can be classified by the irreducible representations of the wave functions involved or more conveniently for a chemist by the orbitals which are involved, that is the nonbonding n , bonding σ , π and antibonding n^* , σ^* and π^* orbitals, for example $n \rightarrow \pi^*$, $\pi \rightarrow \pi^*$, and $\sigma \rightarrow \sigma^*$. Additionally it is

very convenient to classify the transitions as electrically or magnetically allowed or forbidden, that is $|\langle \vec{\mu} \rangle_{NK}|$ and $|\langle \vec{m} \rangle_{KN}|$ is different from or equal to zero.

More important for CD spectroscopy is the classification of chromophores with respect to symmetry operations of the second kind (i, σ and S_n with $n > 2$). An inherently dissymmetric chromophore possesses no symmetry element of the second kind and thus is chiral by itself. In an inherently symmetric chromophore a symmetry element of the second kind exists and thus it is achiral by itself. In **Figure 4**, the enone chromophore is shown as inherently symmetric and inherently dissymmetric. The local symmetry of a chromophore cannot be sharply defined because the chromophore itself is only a qualitative quantity. For CD bands, a characterization by the size of the dissymmetry factor g is possible. For an inherently dissymmetric chromophore, the dissymmetry factor g is about or larger than 10^{-2} , for an inherently symmetric chromophore $g < 10^{-2}$ (mostly $\approx 10^{-4}$) if the transition is electrically allowed and magnetically forbidden. g is larger than 10^{-2} (mostly 5×10^{-3} to 10^{-1}) if the transition is magnetically allowed and electrically forbidden, also for an inherently symmetric chromophore.

What Is a Chromophore?

A chromophore is that part of the molecule where the absorption proceeds and where the main change of

the geometry or electron density, etc. appears after the excitation process. The area of the chromophore is not very well demarcated from the residual parts of the molecule which are not involved in the absorption process. The shading in **Figure 5** demonstrates the continuous variation from the centre of the excitation to the undisturbed residue of the molecule. A carbonyl chromophore with an $n\pi^*$ transition and an olefin chromophore with a $\pi\pi^*$ transition are regarded as two distinct chromophores (**Figure 5**). If the two chromophores are located in a molecule next to each other, an influence on the position of the band and on the intensity of the absorption results. If the interaction is strong enough, the two chromophores have to be considered as one new chromophore.

The number of chromophores in a molecule is very large because of the large number of transitions localized in different parts of the molecule. Also in a group, like the carbonyl group, there is an infinite number of chromophores. One important chromophore for CD spectroscopy besides the $n\pi^*$ transition is a $\pi\pi^*$ transition, located in the carbonyl area and at wavelength lower than 150 nm.

According to Sneath, a molecule can be divided into several spheres (**Figure 6**). The first sphere is the chromophore itself which can be either chiral or achiral. The second sphere is the neighbourhood to the chromophore, the third sphere the area following the second sphere, and so on. The criteria by which the spheres are

Figure 4 The inherently symmetric (left) and inherently dissymmetric (right) enone chromophore.

Figure 5 The enone chromophore as an example for the interaction of two chromophores, that is the 'en' and 'one' chromophore.

Figure 6 Two examples for a decomposition of a molecule into spheres according to Snatzke.

differentiated are the distance and the interaction between the parts of the molecules like conjugation etc. Usually changes in the second sphere can affect the sign and size of the CE whereas substitutions in spheres farther away lead to smaller effects.

The Quantitative Description of the Rotational Strength

Methods for the description of the optical activity are either based on an estimation of the sum over the rotational strengths of all transitions weighted by a dispersion term as in the case of frequency-dependent optical rotation (ORD; denoted as ϕ or $[M]$) or of the rotational strength of one transition in the case of circular dichroism, denoted as $\Delta\epsilon$ or θ (eqn [32]). Numerical quantum mechanical calculations of the rotational strength R^{NK} for a few transitions $|N\rangle \rightarrow |K\rangle$ of a molecule lead nowadays to results of increasing reliability, and thus a determination of the absolute configuration becomes possible with a CD measurement over the spectral region to which the analysed transitions belong. But this is only a development in the right direction, and further advances in computational abilities and resources are necessary. The possibility for numerical calculation is not always available in the chemist's daily work. From this point of view there is no way to renounce the qualitative concepts and semi-qualitative methods used up to now to correlate sign and absolute configuration. Therefore, the following techniques will be discussed in more detail:

1. quantum mechanical calculation of the rotational strength,
2. polarizability theory,
3. one-electron mechanism,
4. model of independent groups (MIG) of Tinoco,
5. exciton model (exciton chirality method).

Quantum Mechanical Calculation of the Rotational Strength

To calculate the rotational strength, reasonably good wave functions for all electronic states should be available. Calculation with a number of semiempirical and *ab initio* techniques have been performed with more or less success. A review of used techniques has been given by Woody in Nakanishi et al. As discussed there, for the calculation of the rotational strength, the electric transition moments can be either evaluated with the dipole-velocity method ($\langle N | \dot{p}_i | K \rangle$, with the linear momentum operator $\dot{p}_i$) which leads to an origin-independent rotational strength R^{NK} but over-estimates errors from inaccurate wave functions far away from the atomic centre, or with the dipole-length method ($\langle N | \mu_i | K \rangle$) which leads to an origin-dependent rotational strength R^{NK} and is not so sensitive to other errors of the wave functions. Up to now the dipole-velocity method has been the method of choice for numerical quantum mechanical calculations. More recent analyses and calculations by Grimme do not support this choice, in contrast to the leading opinion. It seems to us that one may choose the dipole-velocity method or the dipole-length method depending on the kind of molecule and the quality of the calculated wave functions. Furthermore, the extent of taking into account singly and doubly excited configurations is a problem when trying to achieve good results for the direction of the electric and magnetic dipole transition moments and thus for the rotational strength. A newer development can also be found in the use of the density functional theory for the calculation of R^{NK} by Grimme.

The Polarizability Theory

Kirkwood expressed the rotatory power in terms of the polarizabilities and anisotropies of the polarizabilities of groups in the molecule. First-order perturbation theory leads in this case to a perturbation potential expressing the interaction of two transition moment dipoles i, j at a distance R_{ij} where this distance is large compared with the separation of charge in the dipoles. Such terms are important if the molecule contains two or more strong absorption bands near the frequency region where the rotatory dispersion is calculated originating from allowed electric dipole transitions. But even the strongest absorption bands may contribute little to the optical activity by this mechanism if the chromophoric groups are unfavourably disposed relative to each other. However, there has been an improvement in the calculation of the optical rotation with Kirkwood's polarizability theory by using chirality functions as a possibility to find symmetry-adapted functions as shown by Haase and Ruch for asymmetric methane or allene derivatives. The thus obtained electric dipole transition moments are grouped

together to polarizabilities or to polarizability tensor coordinates, respectively. The basis for the description is a second-order perturbation theory of the optical rotation.

The One-Electron Mechanism

Historically, the one-electron mechanism was introduced by Condon and co-workers as an optical activity which originates from the excitation of a single electron in a field of suitable dissymmetry. In the MO concept, the one-electron mechanism is an excitation of one electron to a singly excited electronic configuration of an inherently symmetric chromophore perturbed by chiral surroundings. Depending on the symmetry of the chromophore, the transition is either electrically or magnetically dipole allowed and without the perturbation fulfills the condition that the dot product of the electric and magnetic dipole transition moments of this transition is zero. By the perturbation with groups/atoms in chiral surroundings a magnetically or electrically allowed dipole is induced by borrowing intensity from other transitions of the same chromophore. Often the language ‘intensity is stolen from other transitions’ has been used in the literature, for example ‘contributions to the rotational strength of the $n \rightarrow \pi^*$ transitions are stolen by this mechanism from electric-dipole-allowed $\sigma \rightarrow \sigma^*$ or $\pi \rightarrow \pi^*$ transitions’. There are two possibilities for a perturbation: On the one hand, electronic interactions are responsible for the intensity borrowing which is often called the dynamic coupling model. On the other hand, vibrational processes change the geometry and, by taking into account the dependence of $\langle \vec{\mu} \rangle_{0n}$ and/or $\langle \vec{m} \rangle_{n0}$ on nuclear coordinates, intensity is borrowed by the transition $N \rightarrow K$ via nuclear vibrations from other allowed transitions of the chromophore. Then different vibrational progressions contribute to the UV and CD spectra as shown in **Figure 3**. This mechanism is often called the static coupling or vibronic coupling model. Depending on the type of transitions, a nomenclature system has been introduced by Moscowitz and co-workers and Weigang where the CD of a transition (1) without intensity borrowing is called a case I CD, (2) with intensity borrowing via one forbidden electronic dipole transition is called a case II CD and (3) with intensity borrowing via electrically and magnetically forbidden transitions is called a case III CD. Whereas in case I only progressions with totally symmetric vibrations contribute to the CD, in cases II and III progressions with nontotally symmetric vibrations and vibrational CD bands of the same or different sign can also contribute to an electronic CD band as shown by Weigang, and in by Moscowitz in the book by Snatzke.

The MIG for the Calculation of the Rotational Strength of Large Molecules or Polymers

Tinoco’s aim with the MIG method was to calculate the total rotational strength R^{NK} for a transition $|N\rangle \rightarrow |K\rangle$ for a large molecule or a polymer possessing a large number of equal and different groups, that is chromophores, for which the circular dichroism is given by

$$\begin{aligned} \Delta\varepsilon(\bar{\nu}) &= \frac{B\bar{\nu}}{3} \sum_k R^{NK} \sum_n \sum_k |\langle n|k\rangle|^2 F^{Nnk}(\bar{\nu}) \\ &= \sum_k R^{NK} F^{NK}(\bar{\nu}) \end{aligned} \quad [38]$$

The excited state may or may not be degenerate or accidentally degenerate. In the case of an n -fold degeneracy of the state $|A\rangle$, the excited states $|L\rangle$, linear combinations of the degenerate states $|A\rangle$, contribute to the rotational strength (eqn [39]):

$$R^{0A} = \sum_{L=1}^n R^{NL} = \sum_{L=1}^n \text{Im} \left\{ \langle \vec{\mu} \rangle_{NL} \cdot \langle \vec{m} \rangle_{LN} \right\} \quad [39]$$

For the evaluation of the rotational strength, the molecule is decomposed into different groups i which are at a distance $|\vec{R}_{ij}| = |\vec{R}_i - \vec{R}_j|$ and oriented differently with respect to each other. The operator of the interaction between two groups i, j is given by the potential $\hat{V}_{ij}$. Depending on the assumption for the interaction between the groups, different approximations for the wave functions of the groups are necessary. In the simplest case of completely isolated groups, the wave function of the molecule can then be expressed as a product of the wave functions of the groups. It is assumed that the group electronic wave functions do not overlap, which means that there is no electron exchange between groups. Only the interaction between two groups at a time is considered. Furthermore, it is assumed that singly and doubly excited states on different groups are possible.

To calculate the total rotational strength for a transition, it is necessary to describe the electric and magnetic dipole transition moment operator in an adequate way. Whereas the electric moment operator is the sum of the moments of the different groups, for the magnetic moment operator two contributions have to be taken into account. Analogously to the electric moments, there is a contribution from the magnetic moment of every group. The second contribution comes from the interaction of groups. In a simplified picture, a ‘moving electron’ in one group leads to a magnetic moment in the other group and gives rise to a large contribution to the rotational strength, which resembles the exciton coupling and the coupled oscillator model as discussed in a later section. The rotational strength of a nondegenerate system with

the assumptions given in the preceding text is obtained as follows:

$$\begin{aligned}
 R^{0A} = & \sum_i [\text{Im} \langle \mu \rightarrow \rangle_{i0a} \cdot \langle m \rightarrow \rangle_{ia0} \\
 & - 2 \sum_{j \neq i} \sum_{b \neq a} \frac{\text{Im} V_{i0a,j0b} \{ \langle \mu \rightarrow \rangle_{i0a} \cdot \langle m \rightarrow \rangle_{j0b} \bar{v}_a + \langle \mu \rightarrow \rangle_{j0b} \cdot \langle m \rightarrow \rangle_{ia0} \bar{v}_b \}}{b(\bar{v}_{b0}^2 - \bar{v}_{a0}^2)} \\
 & - \sum_{j \neq i} \sum_{b \neq a} \frac{\text{Im} V_{iab,j00} \{ \langle \mu \rightarrow \rangle_{i0a} \cdot \langle m \rightarrow \rangle_{ib0} + \langle \mu \rightarrow \rangle_{i0b} \cdot \langle m \rightarrow \rangle_{ia0} \}}{b(\bar{v}_{b0} - \bar{v}_{a0})} \\
 & - \sum_{j \neq i} \sum_{b \neq a} \frac{\text{Im} V_{i0b,j00} \{ \langle \mu \rightarrow \rangle_{i0a} \cdot \langle m \rightarrow \rangle_{iba} + \langle \mu \rightarrow \rangle_{iab} \cdot \langle m \rightarrow \rangle_{ia0} \}}{b\bar{v}_{b0}} \\
 & - \sum_{j \neq i} \frac{\text{Im} V_{i0a,j00} \{ \langle \mu \rightarrow \rangle_{iaa} - \langle \mu \rightarrow \rangle_{i00} \cdot \langle m \rightarrow \rangle_{ia0} \}}{b\bar{v}_{a0}} \\
 & - \frac{2\pi}{c} \sum_{j \neq i} \sum_{b \neq a} \frac{V_{i0a,j0b} \bar{v}_{0a} \bar{v}_{0b} \{ (\langle R \rightarrow \rangle_j - \langle R \rightarrow \rangle_i) \cdot (\langle \mu \rightarrow \rangle_{j0b} \times \langle \mu \rightarrow \rangle_{i0a}) \}}{b(\bar{v}_{b0}^2 - \bar{v}_{a0}^2)}] \quad [40]
 \end{aligned}$$

The coupling $V_{irs,jtv}$ between the groups i, j with their singly or doubly excited configurations r, s and t, v is given by the matrix elements

$$V_{irs,jtv} = \int \varphi_{ir} \varphi_{is} \hat{V}_{ij} \varphi_{jt} \varphi_{jv} d\tau \quad [41]$$

The potential energy operator $\hat{V}_{ij}$ of eqn [41] stands for the electrostatic interaction between the groups i and j . $\varphi_{ir}, \varphi_{is}$, etc. are group wave functions, where the first index represents the group and the second index the electronic state of the group r, s , etc. in i and t, v , etc. in j . $\langle \vec{\mu} \rangle_{i0a}$ and $\langle \vec{m} \rangle_{ia0}$ are the electric and the magnetic dipole transition moments of an excitation of a group i for a transition from the ground state $|0\rangle$ to the excited state $|a\rangle$ ($|0\rangle \rightarrow |a\rangle$). $\bar{v}_{a0}$ and $\bar{v}_{b0}$ are the energies given in wavenumbers of the transitions $|0\rangle \rightarrow |a\rangle$ and $|0\rangle \rightarrow |b\rangle$, respectively.

The first term of eqn [40] contributes to the optical activity of a molecule if the transition $|N\rangle \rightarrow |K\rangle$ is electrically and magnetically allowed and the chromophore is inherently dissymmetric. This term represents the optical activity of isolated groups. In the second term the electric and magnetic dipole transition moments on different groups contribute by coupling the groups in their excited states by electrostatic interaction. The interaction of electric and magnetic dipole transition moments of different transitions of one isolated group are described with the third and the fourth term of eqn [40]. The fifth term shows the dependence on the difference of the electric dipole moment of the ground and excited state. This term is – as the fourth term – very small because of the division by $\bar{v}_{a0}$ instead of a difference like $\bar{v}_{a0}^2 - \bar{v}_{b0}^2$. The coupling of the electric dipole transition

moments of two different groups in the sixth term represents the exciton model of two groups if their excited

states are nondegenerate. This is the term which is the origin for the exciton chirality method of Harada and Nakanishi if the two excited states of the coupled electric transition moments are obtained by absorption in different spectral regions. This term corresponds to the theory of coupled oscillators. The interaction between degenerate groups does not contribute to the rotational strength of a polymer here. This effect is discussed in the last section for a system of two chromophores.

Rules for the Determination of the Absolute Configuration

Chirality Functions

For molecules with an inherently symmetric chromophore or molecules which can be formally decomposed into an achiral skeleton and achiral groups, so-called ligands, chirality functions have been developed which allow a quantitative description of chiral phenomena as a function of phenomenological parameters of the ligand. Additionally these functions allow the correlation of the sign of the chirality phenomenon and the absolute configuration of the molecule.

A systematic analysis of such chirality functions, taking advantage of the symmetry properties of the skeleton, has been given by Ruch and Schönhofer. The ligands, the number of which is determined by the chosen binding sites and the symmetry of the skeleton, are at positions where symmetry operations applied to the skeleton permute the ligands on the different possible binding sites and thus create new distinguishable molecules. The binding site of a ligand is correlated with an argument for the ligands in the function, that is the

Figure 7 Achiral skeleton with D_{2d} symmetry and the four substitution positions 1 to 4 for an allene.

arguments $\lambda(l_1)$, $\lambda(l_2)$, etc. correspond to the positions 1, 2, etc. in **Figure 7**. In the approximation of the so-called ‘qualitative completeness’, the chirality function $\chi(l_1, l_2, l_3, l_4)$ for allene derivatives with a skeleton of D_{2d} symmetry and with four binding sites for the ligands which depend on two phenomenological parameters $\lambda(l_i)$, $\mu(l_i)$ for each ligand l_i can be given by

$$\begin{aligned} \chi(l_1, l_2, l_3, l_4) = & \eta_1 [\lambda(l_1) - \lambda(l_2)] [\lambda(l_3) - \lambda(l_4)] \\ & + \eta_2 [\mu(l_1) - \mu(l_2)] [\mu(l_3) - \mu(l_4)] \\ & \times [\mu(l_2) - \mu(l_3)] [\mu(l_2) - \mu(l_4)] [\mu(l_3) - \mu(l_4)] \end{aligned} \quad [42]$$

where η_1 and η_2 are two additional phenomenological parameters. For the optical rotation the phenomenological parameters for a large number of ligands have been determined. Ligand parameters of one and the same ligand are different if they are bound to achiral skeletons of different symmetry and different sites, that is a determined parameter for one special ligand can only be taken for compounds with identical skeletons. There are further restrictions for the description of the optical rotation by chirality functions because of some experimental and theoretical reasons. One restriction is the assumption that the ligands at a binding site of the skeleton have to be invariant under the symmetry operation of the site group. This means that a ligand at a binding site must possess sufficient symmetry to make all properties invariant under the symmetry operation of the skeleton. In spite of this restriction, the chirality function allows us in an excellent way to prove whether molecular theories are suitable to describe chirality phenomena or they allow us to write these theories in a way that shows immediately that they describe a chirality phenomenon. An example of such an application is the rewriting of Kirkwood’s polarizability theory of the optical rotation of methane and allene derivatives by Haase and Ruch.

Sector Rules

To correlate the absolute configuration of a molecule with the sign of the CE of a transition, empirical or theoretical rules are needed. One form of rules is the so-called sector rules which are applicable to inherently symmetric skeletons/chromophores. In this case the

Figure 8 Scheme for developing a sector rule.

molecules have to be decomposed into a symmetric skeleton/chromophore and perturbing atoms. The potential V of the perturbing atoms is expressed by symmetry-adapted functions as shown in Schellman’s general theory for sector rules as

$$V = \sum_{v,i} V_i^v \quad [43]$$

where the V_i^v belong to the i th row of the v th representation of the symmetry group of the inherently symmetric skeleton. The circular dichroism in the chromophore is then induced by the term V_i^v of eqn [43] which belongs to the pseudoscalar representation of the symmetry point group of the chromophore. With this perturbation within the one-electron theory of Condon, Altar and Eyring, the induced CD can be evaluated as a function of the positions of the perturbing atoms or groups. A plausible derivation according to Schellman’s description for a chromophore of C_{2v}/D_{2b} symmetry represented by the plane shown in **Figure 8** can be done as follows: A perturbing atom at the position $P(x, y, z)$ (right) makes the entire system chiral with a certain handedness. The molecule is chiral as long as the perturbing atom is not positioned in one of the symmetry planes of the achiral chromophore, for example in $P(0, y, z)$ (middle). When the perturbing atom is shifted to the position $P(-x, y, z)$ (left), the mirror image of the system in the right part of the figure is obtained. For the resulting molecule a sign change in the CE has to be measured because this molecule is the enantiomer of the initial molecule. If the existence of chiral zero points can be excluded the sign of the CE can only be changed when the perturbing atom crosses one of the symmetry planes of the model molecule (**Figure 8**). All atoms – except fluorine – induce the same sign for the Cotton effect. This means, however, that a sector rule for this model exists which is a quadrant rule for C_{2v} and an octant rule for D_{2b} symmetry. The quadrant rule can change to an octant rule if it is taken into account that a new apparent symmetry plane can be introduced into the molecule by the nodal plane of the π^* orbital of the carbonyl group. The question whether experimentally a quadrant or an octant rule has to be used for the carbonyl chromophore has been discussed in the literature for a very long time.

Figure 9 shows six examples of inherently symmetric chromophores in which the region where atoms induce a CE of different sign are indicated as black or white. The higher the symmetry the larger is the number of sign changes when moving a perturbing atom in space. As a consequence, rules for chromophores with high symmetry are not very reliable.

For the most popular rule, the octant rule for the carbonyl chromophore, an application is demonstrated in Figure 10 for a cyclic ketone. To perform a sector rule the region around the chromophore is divided into sectors by symmetry or nodal planes: Atoms in a symmetry or a nodal plane do not contribute to the CD, the contributions of atoms in neighbouring sectors are always opposite in sign. Spectra of an aromatic system where a sector rule can be applied to the third sphere are given as further examples in Figure 11.

Helicity Rules

Sector rules fail if a chromophore is inherently dissymmetric and the rotational strength is only determined by

Figure 9 Schematic representation of the sector rules for the skeletons or chromophores of C_s , C_{2v} , D_{2h} , C_{3v} , D_{6h} and T_d symmetry according to Schellman.

its internal structure. From the definition of a chromophore given it is easy to imagine that the delimitation of an inherently dissymmetric from an inherently symmetric chromophore is not straightforward. Furthermore, it is difficult to choose atoms in a molecule with which a helical arrangement can be approximately defined. If there is at least one full turn of a helix constituted by a dissymmetric arrangement of groups or atoms that are positioned exactly on a helical line, then the sense of helicity can be assigned unequivocally and a correlation of the sign of the CE can be experimentally or theoretically determined to derive a general rule. Otherwise only a helicity with atoms which are approximately positioned on a helical line can be determined. It has been pointed out by Sneath in the book by Janoschek that such an approximately determined helicity of a molecule – for which a helicity rule can be applied – depends on the viewing angle. In general, this means, to find a helical order in a molecule, one has to select a direction in a chromophore and then has to choose atoms within the chromophore which lay approximately on a helical line with respect to the chosen viewing angle. But the question is which viewing angle has to be chosen, because there are many directions for the selection of an approximate helical order for which one can try to develop a helicity rule. In most cases chemical intuition from experimental experience can help to solve this problem. In some cases the CD of an oriented chromophore in an anisotropic sample (ACD) can help to decide whether there is a helical structure along a special direction or not as discussed by Kuball and Höfer.

Helicity rules have been developed which can be applied to inherently dissymmetric chromophores, such as the enone chromophore shown in Figures 12 and 13, where the chosen atoms are only approximately on a helical line. Many papers have been published concerning the enone chromophore as summarized by

Figure 10 Octant projection of a compound with a carbonyl group showing a CE induced by the second sphere. Each atom outside the symmetry planes contributes to the CD. The contributions of atoms which are in mirror image positions compensate.

Figure 11 The benzene chromophore as an example for the application of sector rules for the third sphere. On the right the schematic representation of the sector rules for the long wavelength 1L_b transitions (a) and for the short wavelength 1L_a transitions (b) are given. The plane of the aromatic system is a nodal plane.

Figure 12 The enone chromophore as an example for the application of helicity rules.

Figure 13 Helicity of the enone chromophore.

Gawronski in the book by Patai and Rappoport. In the simple cases the torsional angle of the enone chromophore determines the sign of the CE where for a P helix ($\omega > 0$) and for an M helix ($\omega < 0$) a positive and a negative CE for the $n\pi^*$ transition result, respectively. Substitution at the chromophore may have dramatic effects and can be responsible for the requirement of a modification of the rule.

The Exciton Chirality Method

Two or more chromophores located nearby in space can constitute a chiral system. An electric dipole–electric dipole interaction between the chromophores shifts and splits the energy levels of their excited states with respect to the interaction-free states. In the case of two identical chromophores, for example in a molecule with at least, or even approximately, the point symmetry group C_2 , the degeneracy is removed (Figure 14).

As a consequence, the UV spectrum is built up from two transitions with different transition moment directions as shown for βR , $\beta'R$ -dimethylmesobilirubin-XIII α (Figure 15) which gives rise to a frequency-dependent degree of anisotropy R (Figure 16). In the case of a molecule of C_2 symmetry the transitions are polarized perpendicular to each other, one transition parallel to the C_2 symmetry axis and the other one in the plane perpendicular to this symmetry axis. For both of these transitions, using the shape of the UV band of the transition of the dipyrnone fragment, the absorptions $\epsilon^\alpha(\bar{\nu})$ and $\epsilon^\beta(\bar{\nu})$ (Figure 17) for βR , $\beta'R$ -dimethylmesobilirubin-XIII α are given by

$$\epsilon(\bar{\nu}) = F^{NK}(\epsilon^\alpha(\bar{\nu}) + \epsilon^\beta(\bar{\nu}) - (\epsilon^\alpha(\bar{\nu}) - \epsilon^\beta(\bar{\nu}))\cos\vartheta) \quad [44]$$

where ϑ is the angle between the dipole transition moments of the fragments and F^{NK} is a factor which takes into account a change of intensity of the monomer band by the interaction in the molecule (Figure 17 left) built

Figure 14 Davydov splitting $2V_{ij}$ of the two degenerate excited states of two interacting identical chromophores in a compound of C_2 symmetry for $\vartheta < \vartheta_0$.

Figure 15 Linear and folded structure of $\beta R, \beta' R$ -dimethylmesobilirubin-XIII α of M helicity and the dipyrromethane ester as the building unit (fragment). Θ is the angle between the mean molecular planes of the dipyrromethane units. The arrows indicate the transition moment directions within the dipyrromethane units which enclose the angle ϑ . The X^*_{22} axis is chosen to be parallel to the C_2 symmetry axis which is the angle bisector through C10 between the mean molecular planes of the dipyrromethane units. In the solution there is an excess of the P conformer in $P \rightleftharpoons M$.

up of the two fragments. In the spectral regions of the absorption bands belonging to the exciton transitions, a positive and a negative CE appears as shown in **Figure 17** (right). Both CEs superpose to a couplet which can be described by bands possessing the shape of the UV spectra as follows

$$\Delta\epsilon(\bar{\nu}) = \frac{4R^{NK\alpha}}{D^{NK\alpha}}(\epsilon^\alpha(\bar{\nu}) - \epsilon^\beta(\bar{\nu}) - (\epsilon^\alpha(\bar{\nu}) + \epsilon^\beta(\bar{\nu}))\cos\vartheta) \quad [45]$$

where $R^{NK\alpha}$ is the rotational strength of the transition α (**Figure 14**) and $D^{NK\alpha}$ the corresponding dipole strength. The fitting of the CD and UV bands of $\beta R, \beta' R$ -dimethylmesobilirubin-XIII α (**Figure 15**) according to eqns [44] and [45] allows to determine the angle ϑ between the dipole transition moments of the fragments.

Using a simple version of the exciton theory, the exciton couplet built up by the CD curves of two identical chromophores i and j of different signs can be described

Figure 16 The UV spectrum ($\blacklozenge$) ($T=80^\circ\text{C}$) and the temperature dependent degree of anisotropy of $\beta R, \beta' R$ -dimethylmesobilirubin-XIII α in ZLI-1695 ($T=28^\circ\text{C}$ ($\blacktriangle$), 43°C ($\bullet$), and 65°C ($\blacksquare$)).

Figure 17 Exciton coupling of the two chromophores of $\beta R, \beta' R$ -dimethylmesobilirubin-XIII α dissolved in ZLI-1695 in the CD and UV spectrum. The dotted and the dashed lines are the calculated contributions of the two exciton bands. The dashed-dotted lines are the calculated CD and UV spectra.

assuming spectral functions of Gaussian form by

$$\Delta\epsilon(\bar{\nu}) = \frac{2\sqrt{\pi}\bar{\nu}_0^2}{2.296 \times 10^{-39}\Delta\bar{\nu}^2} \left[\frac{\bar{\nu}_0 - \bar{\nu}}{\Delta\bar{\nu}} \right] \times \exp \left\{ - \left[\frac{\bar{\nu}_0 - \bar{\nu}}{\Delta\bar{\nu}} \right]^2 \right\} \vec{R}_{ij} \cdot \left(\langle \vec{\mu} \rangle_{iNK} \times \langle \vec{\mu} \rangle_{jNK} \right) V_{ij} \quad [46]$$

Here, $\bar{\nu}_0$ is the centre of the exciton bands and $\Delta\bar{\nu}$ the half bandwidth of the single exciton bands α and β . The transition moment of the transition α or β can be expressed by

$$\langle \vec{\mu} \rangle^{\alpha, \beta} = \frac{1}{\sqrt{2}} \left(\langle \vec{\mu} \rangle_{iNK} \mp \langle \vec{\mu} \rangle_{jNK} \right) \quad [47]$$

where the upper sign belongs to the α band and the lower sign to the β band. The pseudoscalar product $\vec{R}_{ij} \cdot (\langle \vec{\mu} \rangle_{iNK} \times \langle \vec{\mu} \rangle_{jNK})$ in eqn [46] determines the sign of the couplet. The Davydov splitting $2V_{ij}$ (**Figure 14**) between the energy states N, K of the groups i and j is given by

$$V_{ij} = \frac{(\langle \vec{\mu} \rangle_{iNK} \cdot \langle \vec{\mu} \rangle_{jNK}) - 3\vec{R}_{ij}^2 (\langle \vec{\mu} \rangle_{iNK} \cdot \vec{R}_{ij}) (\langle \vec{\mu} \rangle_{jNK} \cdot \vec{R}_{ij})}{R_{ij}^3} \quad [48]$$

where $\vec{R}_{ij}$ is a vector pointing from group i to group j and the Davydov splitting is smaller than the half bandwidth. For derivation of the exciton theory it is assumed that the interacting groups are far away from each other and thus the distance of the chromophores $R_{ij} = |\vec{R}_{ij}|$ can be chosen independently from the extension of the chromophores. This is a presupposition not fulfilled in most cases of application of the theory. Furthermore, one has to take into account an effect given above but often not realized in the literature: A change of sign of the couplet appears without a change of the helicity if the sequence of the states resulting from the Davydov splitting $2V_{ij}$ (eqn [48]) is interchanged (**Figure 14**; sign change of V_{ij}). The sign change depends on the angle ϑ between the transition moment directions. For $V_{ij} = 0$ there is a chiral zero of the 'chirality function $\Delta\varepsilon(\bar{\nu})$ ' (eqn [46]) that is $\Delta\varepsilon = 0$, in spite of the fact that the system is chiral. V_{ij} is zero when $\vartheta = \vartheta_0$ and $\cos \vartheta_0 = \vec{R}_{ij} \cdot \langle \vec{\mu} \rangle_{iNK} / |\langle \vec{\mu} \rangle_{iNK}| \cdot |\langle \vec{\mu} \rangle_{jNK}|$. If ϑ is approximately, 90° and thus near a chiral-zero position, an experimental assignment of the α and β transitions can help to avoid an incorrect conclusion. This is also of importance because the vector $\vec{R}_{ij}$ is strongly dependent on the origin not only in its length but also in its orientation with respect to the molecular skeleton. This fact makes it difficult to estimate the sign of the couplet because of the chiral zero ($V_{ij} = 0$) given by the uncertainty of the chosen ϑ . This problem has to be considered from the point of view that in most applications of the exciton chirality method the theoretical condition that the distance between the chromophores is large compared to their extension is not well fulfilled.

Taking these discussed problems into account, the following rule holds: Positive (P) and negative (N) helicities lead always to positive (positive CE at the longer wavelength side and negative CE at the shorter wavelength side) and negative couplets of the CD as long as the angle ϑ between the transition moment direction is smaller than ϑ_0 with $0 \leq \vartheta \leq \vartheta_0$. Here the helicity of the structure is defined as positive, when the geometrical arrangement gives rise to a clockwise rotation of the electric dipole transition moment in the foreground if looking along the axis about which the rotation is

performed and vice versa. Choosing suitable values for $|R_{ij}|$ and taking care that the dipole strength of the absorption band of the exciton couplet is approximately twice the dipole strength of the monomer's absorption which build up the inherently dissymmetric molecule, reliable conclusions for the absolute configuration can be obtained. So far, the exciton chirality method is a useful method for establishing absolute configurations and conformations of organic compounds in solution.

To improve the reliability of the conclusion from the CD and UV measurements of isotropic solutions, the assignment of the exciton transitions should be determined experimentally. For the evaluation of the correct dihedral angle, polarized spectroscopy can be used as a very suitable additional information for the assignment. Since, in most cases, this information has not been taken into account, the value of such an analysis is demonstrated in the following with $\beta R, \beta' R$ -dimethylmesobilirubin-XIII α and its constituting unit dipyrnone (**Figure 15**) according to Bauman and co-workers. Owing to the assumed C_2 symmetry of $\beta R, \beta' R$ -dimethylmesobilirubin-XIII α the transition moments either lie parallel to the C_2 symmetry axis or in a plane perpendicular to it.

From the degree of anisotropy R in **Figure 14** it follows that the β and the α transitions are of $A \rightarrow A$ and $A \rightarrow B$ symmetry, respectively, for $\vartheta < \vartheta_0$. From the temperature dependence of the degree of anisotropy (**Figure 16**) with the help of a computational simulation the tensor coordinates of the absorption tensor and the dipole strength tensor D^*_{ii} with respect to the principal axes of the order tensor can be obtained. Furthermore, information about the orientational order of the molecule in the used anisotropic system as stretched polymers or ordered liquid crystal phases can be obtained too.

To determine the transition moment directions in the dipyrnone units and of the α -transition of $\beta R, \beta' R$ -dimethylmesobilirubin-XIII α which are not determined by symmetry, the ratio V (eqn [49], derived from a simple version of the exciton theory) was used as further information to select possible mathematical solutions for the transition moment direction of the dipyrnone unit.

$$V = \frac{D_{22}^{*\beta}}{D_{11}^{*\alpha} + D^{*\alpha}} = \frac{1 + \cos \vartheta}{1 - \cos \vartheta} \approx \frac{\varepsilon^\beta(\bar{\nu}_{\max})}{\varepsilon^\alpha(\bar{\nu}_{\max})} \quad [49]$$

This ratio determined from the $\varepsilon^\alpha(\bar{\nu})$ and $\varepsilon^\beta(\bar{\nu})$ curves of **Figure 17** and the $\varepsilon_{22}(\bar{\nu})$ and $\varepsilon_{11}(\bar{\nu}) + \varepsilon_{33}(\bar{\nu})$ curves from **Figure 18** allows to check the reliability of the experimental results obtained from UV and CD spectroscopy in isotropic media and from polarized UV spectra. In the example given here, the ratio V from both results is equal within 30%, which is in fair agreement with the expected accuracy of the determined reduced spectra. In **Figure 18** the reduced UV spectra for the

Figure 18 The tensor coordinates ϵ_{11}^* (.....■.....), ϵ_{22}^* (---●---), ϵ_{33}^* (.....▲.....) of the absorption tensor and the sum $\epsilon_{11}^* + \epsilon_{33}^*$ (—▼—) of $\beta R, \beta' R$ -dimethylmesobilirubin-XIII α in ZLI-1695. $\epsilon_{11}^* + \epsilon_{33}^*$ is the long wavelength (α band: A $\rightarrow$ B) and ϵ_{22}^* is the short wavelength (β band: A $\rightarrow$ A) exciton band.

exciton coupling are given. The analysis for this special example demonstrates how useful it can be to determine and analyse polarized spectroscopy for the use of the exciton chirality method. In particular, the angle of the chiral zero can be estimated to avoid errors resulting from interchanging the position of the α and β states in the term scheme (Figure 14).

Symbols

$\mathbf{A}$	differential Mueller matrix
c	concentration (mol l^{-1}), velocity of light
d	pathlength (cm)
D^*	order parameter
$D_{ij}^{NK}, D_{ij}^{NnKk}$	$\sqrt{3(g_{2233}^* - g_{1133}^*)/2}$ dipole transition moment tensor
$f(\alpha, \beta, \gamma)$	orientational distribution function
$\mathbf{F}$	Mueller matrix
F^{NnKk}, G^{NnKk}	spectral functions for $ Nn\rangle \rightarrow Kk\rangle$
g_{ijkl}	orientational distribution coefficients
h	Planck constant
$\mathbf{I}$	identity matrix
I	light intensity
$[M]$	molar rotation
M	molecular mass (g mol^{-1})
n	refractive index, number density
N_A	Avogadro constant
q	concentration ($\text{g}/100 \text{ cm}^3$)
R^A	anisotropic rotational strength of a transition
$R_{ij}^{NK}, R_{ij}^{NnKk}$	rotational strength tensor
$\mathbf{S}$	Stokes vector
S^*	order parameter $= (3g_{3333}^* - 1)/2$
X_{ij}, Y_{kl}	tensors of second rank for the molecules and the phase, respectively
α, β, γ	Euler angles
$[\alpha]$	specific rotation
$\Delta\epsilon$	circular dichroism
$\Delta\epsilon_{ij}$	circular dichroism tensor
ϵ	absorption coefficient
ϵ_{ijk}	Levi-Civita tensor
$[\theta]$	molar ellipticity
$\mu = \kappa, \lambda$	roots of the characteristic polynomial of $\text{Det}(\mathbf{A}' - \mu\mathbf{I}) = 0$
$\bar{\nu}$	wavenumber
ρ	density (g cm^{-3})
ϕ, α	optical rotation in rad, degree

Introduction

Homochirality, such as the dominance of the left-handed α -amino acids owing to symmetry breaking arising from the nuclear weak interaction and other mechanisms, is the basis of biomolecular enantioselection. The ‘wrong’ chiral form can, for example as a compound in a drug, lead to unwanted and even dangerous effects. Thus, the phenomenon of ‘chirality’ itself as well as new ideas for exploiting it are of current interest.

Nowadays, chirality is often discussed from the point of view of such basic phenomena as charge conjugation, parity and time reversal (CPT symmetry). But for a ‘way in’ to chirality in chemistry and physics, the different occupation of space by two enantiomers, inherent in the definition of Kelvin, and its extension to statistical systems by Avnir covers most of the problems. Kelvin’s definition provides a background for a hierarchy of chiral objects or structures through four levels: atoms, molecules, phases with long-range orientational and positional order, and the shape of objects. Long-range orientational and positional order in a phase can lead to a microscopic chiral structure of particles in the phase. The shape of a phase is its macroscopic appearance, for example the crystal habit. Chirality that is caused by long-range orientational and positional order will be called ‘suprastructural phase chirality’ in the following.

Methods are required to detect chirality. A so-called ‘chirality observation’ answers the question whether the system is chiral or not with yes or no. Then, a ‘chirality measurement’ yields a value and a sign for a quantity that gives information about the chirality of the molecules or the phases but, in general, gives no measure for chirality itself.

One of the most popular methods for detecting chirality is the measurement of the optical activity. A chiral object rotates the plane of polarization of linearly polarized light and generates ellipticity in the region of absorption bands because of the different refractive indices and absorption coefficients for left- and right-circularly polarized light – circular birefringence and dichroism. The main interest in circular dichroism (CD) spectroscopy is based on three applications. First, CD spectroscopy can be applied as a very specific and sensitive fingerprint method in analytical chemistry; CD

spectrometer units have even been developed as detection devices in chromatography. Second, the determination of the absolute configuration of a molecule is of great interest in spite of the fact that the CD method is not an absolute method in contrast to Bijvoet's method. Thus, many rules, so-called sector and helicity rules, for different classes of compounds have been developed for electronic transitions in the visible and UV spectral region to correlate the CD with the absolute configuration. For vibrational transitions in the IR spectral region, the existence of such correlation is the exception, not the rule.

The CD, $\Delta\epsilon$, of an isotropic system is one-third of the trace of a pseudo-tensor of second rank:

$$\Delta\epsilon = \frac{1}{3}(\Delta\epsilon_{11} + \Delta\epsilon_{22} + \Delta\epsilon_{33}) \quad [1]$$

To increase the quantity of information available for a molecule, the three coordinates $\Delta\epsilon_{ii}$ ($i=1,2,3$) of $\Delta\epsilon$ in eqn [1], that is the CD of oriented molecules in anisotropic samples (ACD), can be measured.

There is a third problem for which chirality information is of current interest: anisotropic phases are often stabilized by chiral structures. Apart from chiral structures with enantiomorphic crystals of chiral compounds, suprastructural chirality exists in liquid crystal phases built up by chiral molecules as in the cholesteric phases and the smectic C* phases. Even liquid crystalline phases with suprastructural chirality originating in achiral, so-called banana-shaped molecules, seem to be possible. Anisotropic polymer films with chiral structures have been found. It can be anticipated that chiroptical spectroscopy with anisotropic chiral systems will lead to new questions and answers.

Birefringence and Dichroism of Chiral Isotropic and Chiral Anisotropic Phases

Optical Rotatory Dispersion and Circular Dichroism in Isotropic Dissymmetric Phases

The interaction of light with an isotropic dissymmetric solution leads to a left- and a right-circularly polarized light beam for which distinct refractive indices n_L and n_R as well as absorption coefficients ϵ_L and ϵ_R exist owing to the diastereomeric interaction between light and the chiral system. The plane of polarization of the incident linearly polarized light is rotated by an angle ϕ (optical rotation in rad) that is proportional to the circular birefringence $n_L - n_R$,

$$\phi = \pi \bar{\nu} d (n_L - n_R) \quad (\text{rad}) \quad [2]$$

where d is the pathlength of the sample in cm and $\bar{\nu}$ is the wavenumber of the incident light in cm^{-1} . The specific rotation $[\alpha]$ for a fluid or solid compound is defined with

respect to the density ρ (g cm^{-3}) or for a solution with respect to a concentration q in $\text{g}/(100 \text{ cm}^3 \text{ solution})$ and the angle α in degree:

$$[\alpha] = \frac{10 \alpha}{\rho d} = \frac{10^3 \alpha}{qd} \quad \left(\frac{\text{deg cm}^3}{\text{g dm}} \right) \quad [3]$$

The molar rotation $[M]$ can be expressed by

$$[M] = \frac{[\alpha]M}{100} = \frac{100 \alpha}{cd} \quad \left(\frac{\text{deg cm}^3}{\text{mol dm}} \right) \quad [4]$$

where M is the molecular mass in g mol^{-1} and c (mol l^{-1}) the concentration. In the region of an absorption band, both circularly polarized waves superpose and the light becomes elliptically polarized with an ellipticity $\tan\theta$ given by

$$\begin{aligned} \tan \theta &= \frac{10^{-\epsilon_L cd/2} - 10^{-\epsilon_R cd/2}}{10^{-\epsilon_L cd/2} + 10^{-\epsilon_R cd/2}} \cong \theta \\ &= \frac{\ln 10}{4} (\epsilon_L - \epsilon_R) cd = 0.5757 \Delta\epsilon cd \end{aligned} \quad [5]$$

Instead of the circular dichroism $\Delta\epsilon = \epsilon_L - \epsilon_R$, often the molar ellipticity $[\theta]$ is used:

$$[\theta] = \frac{100\theta}{cd} \approx 3300 \Delta\epsilon \quad [6]$$

Because there are two independent waves propagating through the sample (Figure 2), the Lambert–Beer law does not hold,

$$I = I_0 10^{-\bar{\epsilon} cd} \cosh \left(\frac{2303}{2} (\epsilon_L - \epsilon_R) cd \right) \quad [7]$$

but the deviation is in most cases negligible. $\bar{\epsilon}$ is the average absorption of the sample:

$$\bar{\epsilon} = \frac{1}{2}(\epsilon_L + \epsilon_R) \quad [8]$$

The chirality measurements (Figure 1), that is circular dichroism (CD) and optical rotatory dispersion (ORD), and the wavenumber dependence of the molar rotation, are designated together as the Cotton effect (CE). CD and ORD are quantitatively correlated by a Kramers–Kronig transformation. The Kramers–Kronig transformation can be used to check CD measurements by ORD measurements and vice versa by comparing calculated and experimental results.

Anisotropic Samples

The anisotropy of systems is a widespread phenomenon in nature. The description as anisotropic means that a material has different properties along different

directions in space. This anisotropy, caused by long-range orientational and positional order, can be homogeneous, statistically homogeneous or periodically homogeneous. These microscopic structures, for example the screw axis of an NaClO_3 crystal or the pitch of the helical structure in a cholesteric or smectic C^* phase, have to be taken into consideration when, for example, an internal periodicity yields internal reflection of circularly polarized light in the visible or infrared spectral region.

The Concept of Eigenstates of Light

The interaction of light with a material, described by the Jones or Mueller calculus, leads to the concept of eigenstates. These states are determined by the symmetry of the material that is penetrated by the light (**Table 1**). An eigenstate of light refers to light that propagates through a material without changing its state of polarization. For isotropic materials, all states of polarization, and hence also unpolarized light, are eigenstates. Inherently dissymmetric isotropic solutions possess left- and right-circularly polarized light as the two orthogonal eigenstates. For anisotropic uniaxial and biaxial materials, the eigenstates are two orthogonal linearly polarized light beams, whereas in complex systems, for example in chiral anisotropic systems, the eigenstates are two orthogonal elliptically polarized light beams (**Figure 2**).

The linearly, elliptically or circularly polarized eigenstates propagate with different velocities because of the

different refractive indices. Different absorption of the two independent light beams leads to dichroism. Thus, each of the eigenstates has its own and distinct refractive index and molar decadic absorption coefficient (**Table 1**). The plane light waves of the two eigenstates interfere after passing the sample to form an elliptically polarized light beam with an ellipticity and an azimuth different from that of the incident light (**Figure 2**), in general. Its intensity may be less than that of the incident light beam. Linear and circular eigenstates and thus linear and circular birefringence and dichroism of a sample can be seen as two limiting cases of elliptical birefringence and elliptical dichroism.

Chiral Anisotropic Systems

A chiral system is a system that is not superposable on its mirror image. The number of independent measurements of different kinds needed to identify the sample as chiral depends on the knowledge of the system. If it is known, for example, that the system is an isotropic dissymmetric phase, one optical measurement is sufficient, whereas for an anisotropic uniaxial system more than one measurement is demanded. For the latter case, the wavenumber dependence of the ellipticity and the rotation of the plane of polarization can be measured. Here the dispersion of the circular birefringence and dichroism can be, but needs not be, different from that of the linear birefringence and dichroism (**Figure 3**). Another possibility is the measurement of the rotation of the plane of polarization and the ellipticity for different azimuth orientations of the sample about the axis of propagation of the light beam.

The CD of Oriented Molecules: ACD Spectroscopy

Phenomenology of the CD of Anisotropic Phases (ACD) without Suprastructural Chirality

The two eigenstates of light emerging from a homogeneous sample superpose in accordance with their different optical pathlengths. The azimuth and the ellipticity are then given by the Stokes vector $\underline{s}^d$:

$$\underline{s}^d = \underline{F} \cdot \underline{s}^0 \quad [9]$$

Figure 1 A positive Cotton effect (CE), that is the CD (---) and ORD (...), and a UV absorption band (—).

Table 1 Material constants for birefringence and dichroism

Two orthogonal eigenstates of light	Refractive indices (n) and absorption coefficients (ϵ)	Birefringence	Dichroism	Mean absorption
Linearly polarized light	$n_1, \epsilon_1; n_2, \epsilon_2$	$n_1 - n_2$	$\epsilon_1 - \epsilon_2$	$\frac{1}{2}(\epsilon_1 + \epsilon_2)$
Elliptically polarized light	$n_{EL}, \epsilon_{EL}; n_{ER}, \epsilon_{ER}$	$n_{EL} - n_{ER}$	$\epsilon_{EL} - \epsilon_{ER}$	$\frac{1}{2}(\epsilon_{EL} + \epsilon_{ER})$
Circularly polarized light	$n_L, \epsilon_L; n_R, \epsilon_R$	$n_L - n_R$	$\epsilon_L - \epsilon_R$	$\frac{1}{2}(\epsilon_L + \epsilon_R)$

Figure 3 Dispersion of linear and circular birefringence and dichroism, ϕ_{LD} , θ_{LD} , ϕ_{CD} , θ_{CD} ($\Delta\epsilon$) within an absorption band of a chiral molecule.

where $\mathbf{F}$ is the Mueller matrix and $\underline{s}^0$ the Stokes vector of the incident light. In $\underline{s} = \{s_0, s_1, s_2, s_3\}$, s_0 is the intensity whereas $\underline{s} = \{s_1, s_2, s_3\}$ describes the state of polarization (the notation $\{ \}$ indicates a column vector). For a non-depolarizing medium,

$$\mathbf{F} = \exp(-2nd\mathbf{A}) \quad \text{with} \quad \mathbf{A} = \begin{pmatrix} c' & b_1 & b_2 & b_3 \\ b_1 & c' & a_3 & -a_2 \\ b_2 & -a_3 & c' & a_1 \\ b_3 & a_2 & -a_1 & c' \end{pmatrix} = \mathbf{A}' + c'\mathbf{I} \quad [10]$$

is obtained. d is the pathlength and n the number of particles in a unit volume. $\mathbf{I}$ is the identity matrix. It is

convenient to rewrite the Mueller matrix in the form

$$\mathbf{F} = \exp(-2ndc')\mathbf{\Lambda}, \quad \text{with } \mathbf{\Lambda} = \exp(-2nd\mathbf{A}') \quad [11]$$

As shown by Schönhofer and co-workers $\mathbf{\Lambda}$ can be rewritten as a matrix polynomial of third degree:

$$\mathbf{\Lambda} = a_0(\mathbf{A}')^3 + a_1(\mathbf{A}')^2 + [(\lambda^2 - \kappa^2)a_0 + c_2]\mathbf{A}' + [(\lambda^2 - \kappa^2)c_1 + c_3]\mathbf{I} \quad [12]$$

$$\begin{aligned} a_0 &= -\frac{1}{\kappa^2 + \lambda^2} \left[\frac{1}{\kappa} \sinh(2nd\kappa) - \frac{1}{\lambda} \sin(2nd\lambda) \right] \\ a_1 &= \frac{1}{\kappa^2 + \lambda^2} [\cosh(2nd\kappa) - \cos(2nd\lambda)] \\ a_2 &= -\frac{1}{\kappa^2 + \lambda^2} [\kappa \sinh(2nd\kappa) + \lambda \sin(2nd\lambda)] \\ a_3 &= \frac{1}{\kappa^2 + \lambda^2} [\kappa^2 \cosh(2nd\kappa) + \lambda^2 \cos(2nd\lambda)] \end{aligned} \quad [13]$$

with $\kappa_{\pm} = \{\frac{1}{2}(\vec{b}^2 - \vec{a}^2 + 4(\vec{a} \cdot \vec{b})^{1/2} \pm (\vec{b}^2 - \vec{a}^2))\}^{1/2} \geq 0$. For a homogeneous medium with large linear and circular birefringence and dichroism effects, all elements of the differential Mueller matrix A' (for the birefringence $\vec{a} = \{a_1, a_2, a_3\}$ and for the dichroism $\vec{b} = \{b_1, b_2, b_3\}$ in eqn [12]) have to be taken to evaluate the azimuth and ellipticity of the emerging light. The elements a_2 and b_2 are responsible for the optical rotation and for the CD, respectively, and a_1 and a_3 represent the anisotropy of the refractive index of linear polarized light, whereas b_1 and b_3 belong to the corresponding linear dichroism. Because there are six unknown parameters for the anisotropy (eqn [12]), six different measurements made by rotating the sample and measuring with a light beam propagating in different directions within the sample are needed to determine the optical constants. Measuring the dispersion of the ACD or the optical rotatory power of an oriented ensemble (AORD) does not yield new and independent information (Figure 3).

The ACD measurement $\Delta\epsilon^A$ with light propagating parallel to the optical axis of a uniaxial phase is a chirality measurement, but one has to take care to avoid artefacts. A check on the reliability of such a measurement can be obtained by measuring the CD with different sample azimuths rotated around the direction of propagation of light. The CD signal has to be independent of the orientation of the azimuth of the sample. Measurements of the optical effects with a light beam propagating perpendicularly to the optical axis are very difficult to perform because of the artefacts that may be caused by interference with the linear birefringence and dichroism. At present it does not seem possible to overcome the experimental problems with instruments working on the basis of polarization modulation. These experimental problems can be solved using other techniques, for example by measuring the state of polarization of the light, but solving the experimental problem does not solve the whole problem. A measurement with a light beam propagating perpendicularly to the optical axis is not a chirality measurement; that is, measuring two anisotropic phases of enantiomers with a light beam propagating perpendicularly to the optical axis does not yield values that are equal in their absolute value and different in sign, because of the interference with linear effects. The question is whether the measured quantity can be decomposed into an achiral and a chiral part ($\Delta\epsilon_2^A$), that is whether chirality information can be extracted from the data obtained. For a uniaxial system, the following relation can be derived from b_2 :

$$\Delta\epsilon = \frac{1}{3}(\Delta\epsilon^A + 2\Delta\epsilon_2^A) \quad [14]$$

For light polarized parallel and perpendicular to the optical axis and propagating perpendicularly to this axis, with the molar decadic absorption coefficients ϵ_1 and ϵ_2

for a uniaxial system, an equation analogous to eqn [14] is obtained:

$$\epsilon = \frac{1}{3}(\epsilon_1 + 2\epsilon_2) \quad [15]$$

A measurable macroscopic property of the anisotropic phase is then given by the tensor coordinates Y_{kl} as given by Kuball and colleagues

$$Y_{kl} = \sum_{ij} g_{ijkl} X_{ij} \quad [16]$$

(Three tensors are of particular importance for ACD spectroscopy: the transition moment or the absorption tensor (D_{ij}^{NK} or ϵ_{ij}), the rotation or the CD tensor (R_{ij}^{NK} or $\Delta\epsilon_{ij}$) and the order tensor (g_{ij33}). For molecules without any symmetry, the principal axes of the three tensors do not coincide: x_i^+ for D_{ij}^{NK} or ϵ_{ij} , x_i^o for R_{ij}^{NK} or $\Delta\epsilon_{ij}$, and x_i^* for g_{ij33} .)

In eqn [16] X_{ij} is a tensor of rank 2 that describes a molecular property. With the orientational distribution function of the molecules in the anisotropic sample $f(\alpha, \beta, \gamma)$, where α, β, γ are the Eulerian angles, the orientational distribution coefficients g_{ijkl} (eqn [17]) define a set of two different tensors of rank 2 with respect to the transformation of the molecule-fixed (g_{ijkl} : indices ij for each pair of kl) as well as the space-fixed (g_{ijkl} : indices kl for each pair of ij) coordinate system:

$$g_{ijkl} = \frac{1}{8\pi^2} \int f(\alpha, \beta, \gamma) a_{ik} a_{jl} \sin\beta \, d\alpha \, d\beta \, d\gamma \quad [17]$$

a_{ij} is an element of the transformation matrix from the space-fixed x_i^+ to the molecule-fixed x_i coordinate system. For a sample possessing at least a C_3 symmetry axis (uniaxial system) and a light beam propagating along this direction, the circular dichroism of the anisotropic sample $Y_{33} = \Delta\epsilon^A$ is obtained:

$$\Delta\epsilon^A = \sum_{ij} g_{ij33} \Delta\epsilon_{ij} \quad [18]$$

$X_{ij} = \Delta\epsilon_{ij}$ is the circular dichroism tensor of the molecules. According to eqn [14], the CD value $\Delta\epsilon_2^A$ for light propagating perpendicularly to this axis, the optical axis, can be evaluated. Because of the interference with linear birefringence and dichroism, the present authors have not yet been able to measure $\Delta\epsilon_2^A$.

For light polarized parallel to the optical axis and propagating perpendicularly to it, it follows that,

$$\epsilon_1 = \sum_{ij} g_{ij11} \epsilon_{ij} \quad [19]$$

$X_{ij} = \epsilon_{ij}$ is the absorption tensor of the molecules. The correlation between the second pair of indices of the orientational distribution coefficient and the numbering

of the tensor coordinates of the measurable quantity gives rise to an interesting phenomenon. For the ACD ($\Delta\epsilon^A$, eqn [18]) the indices of the coordinates g_{ijkl} are determined by the direction of propagation of light with respect to the molecular frame $kl=33$. This is due to the fact that the CD effect for molecules is given by the projection of the molecular properties on the propagation direction of the light. For polarized absorption spectroscopy, the projection of the molecular properties onto the direction of polarization of the light beam is decisive, that is $kl=11, 22$. This means that the numbering of the absorption tensor is obtained from the polarization direction of the light with respect to the molecular frame, whereas for the ACD the direction of propagation of the light wave is decisive.

The Experimental Determination of the Molecular Tensors $\Delta\epsilon_{ij}$ and ϵ_{ij}

The Equations for the ACD

The result of a CD measurement of an anisotropic sample is a weighted sum of the three quantities $\Delta\epsilon_{ii}$ (eqns [18] and [20]). The weighting factors are the orientational distribution coefficients. For a light beam propagating along a direction of at least a C_3 symmetry axis of a sample, the circular dichroism $\Delta\epsilon^A$ (eqn [18]) is a chirality measurement; this condition is fulfilled for a chiral nematic phase unwound by an electric field when the light beam propagates along the optical axis (x'_3), the nematic director. If the orientation of the principal axes of the order tensor g_{ij33} relative to the molecular frame is temperature-dependent, one may use for the ACD:

$$\Delta\epsilon^A = \sum_{ij} a_{ij}^2 g_{ij33}^* \Delta\epsilon_{ii}^0 \quad [20]$$

The eigenvalues $\Delta\epsilon_{ii}^0$ describe the molecular property $\Delta\epsilon_{ij}$ in its system of principal axes. The terms a_{ij} are the elements of the matrix that transforms the x_i^* coordinates into the x_i^0 coordinates.

For uniaxial systems, the order parameters S^* and D^* may be introduced instead of g_{ij33}

$$S^* = (3g_{3333}^* - 1)/2 \quad [21]$$

$$D^* = \sqrt{3}(g_{2233}^* - g_{1133}^*)/2 \quad [22]$$

They refer to the optical axis of the sample, which is chosen as the space-fixed x'_3 axis, and to the molecule-fixed x_i^* coordinate system. Whereas S^* characterizes the order of the orientation of the molecule-fixed x'_3 axis – the orientation axis – with respect to the optical axis of the uniaxial phase, the parameter D^* is a measure of the deviation from a rotational symmetric distribution function for the molecules about their x'_3 axis.

The principal axes of g_{ij33} are fixed by symmetry for molecules with a point symmetry group different from C_1 , C_2 , C_n , C_s and C_{2v} . For the latter point groups, the orientations of the x_i^* axes with respect to the molecular skeleton have to be determined experimentally; the orientations of the x_i^* axes vary, in general, with temperature. The two order parameters S^* and D^* can be measured, albeit with the use of some approximations, for example by IR, VIS, UV, or NMR spectroscopy.

If the temperature dependence of the orientation of the x_i^* axes can be neglected, or if these axes are fixed by symmetry, $\Delta\epsilon^A$ can be conveniently described as

$$\Delta\epsilon^A - \Delta\epsilon = (\Delta\epsilon_{33}^* - \Delta\epsilon)S^* + \frac{1}{\sqrt{3}}(\Delta\epsilon_{22}^* - \Delta\epsilon_{11}^*)D^* \quad [23]$$

From $\Delta\epsilon^A - \Delta\epsilon$ and S^* and D^* measured as functions of temperature, the quantities $3(\Delta\epsilon_{33}^* - \Delta\epsilon) = 2\Delta\epsilon_{33}^* - \Delta\epsilon_{22}^* - \Delta\epsilon_{11}^*$ and $\Delta\epsilon_{22}^* - \Delta\epsilon_{11}^*$ can be obtained. Because $\Delta\epsilon_{22}^A$ is not available experimentally at present, $\Delta\epsilon$ (eqn [1]) can be used to calculate the tensor coordinates $\Delta\epsilon_{ij}^*$.

To account for the contributions of the different vibrational transitions, the anisotropic rotational strength R^A for the electronic transition $|N\rangle \rightarrow |K\rangle$ is obtained by integrating over the spectral region of an absorption band:

$$R^A = \frac{3}{B} \int \frac{\Delta\epsilon^A(\bar{\nu})}{\bar{\nu}} d\bar{\nu} = 3 \sum_{ij} g_{ij33} R_{ij}^{NK};$$

$$\frac{3}{B} = 22.96 \times 10^{-40} \quad (\text{cgs}) \quad [24]$$

For an isotropic solution, $g_{ij33} = \frac{1}{3}\delta_{ij}$ and R^A becomes the rotational strength for the transition $|N\rangle \rightarrow |K\rangle$:

$$R^{NK} = \frac{3}{B} \int \frac{\Delta\epsilon(\bar{\nu})}{\bar{\nu}} d\bar{\nu} = \sum_i R_{ii}^{NK} \quad [25]$$

δ_{ij} is the Kronecker symbol. The tensor coordinates for the rotational strength tensor (tensor of rotation) can be evaluated experimentally as

$$R_{ij}^{NK} = \frac{1}{B} \int \frac{\Delta\epsilon_{ij}(\bar{\nu})}{\bar{\nu}} d\bar{\nu} \quad [26]$$

For allowed electric dipole transitions, the contributions from vibrational coupling can be neglected. In the case of a forbidden electric or a magnetic dipole transition, there should be contributions from the vibronic coupling and intensity borrowing from other transitions via vibrations of the molecules.

The magnitude of the dissymmetry factor $g = 4R^{NK}/D^{NK}$ can be 10^{-1} , 10^{-3} , 10^{-4} for an inherently dissymmetric chromophore, an $n\pi^*$ transition and a $\pi\pi^*$

transition, respectively, where D^{NK} is the dipole strength (see eqn [31]).

The Equations for the Polarized Absorption

For an anisotropic sample, the molar decadic absorption coefficient for light polarized parallel (ε_1) and perpendicular (ε_2) to the optical axis of a uniaxial sample follows from eqns [19] and [15]:

$$\varepsilon_k = \sum_{i,j} g_{ijk} \varepsilon_{ij} = \sum_{i,j} a_{ij}^* g_{ijk}^* \varepsilon_{ii}^+, \quad k = 1, 2 \quad [27]$$

ε_{ii}^+ are the absorption coefficients of a completely oriented system of molecules for light beams linearly polarized parallel to the x_i^+ axes (principal axes of ε_{ij}). The a_{ij} in eqn [27] are the elements of the matrix that transforms the x_i^* coordinates into the x_i^+ coordinates. The orientational distribution coefficients g_{ij33} have to be used in the following instead of g_{ij11} because, compared to the experimental situation of the CD measurement, the sample is rotated about an axis perpendicular to the propagation direction of the light beam by 90° . The ε_{ii}^+ terms are related to the absorption coefficient of the isotropic solution, analogously to $\Delta\varepsilon$, by eqn [28]:

$$\varepsilon = \frac{1}{3}(\varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33}) \quad [28]$$

If there is no temperature dependence of the x_i^* axes, an appropriate description of the anisotropic absorption is given by

$$\varepsilon_1 - \varepsilon = (\varepsilon_{33}^* - \varepsilon)S^* + \frac{1}{\sqrt{3}}(\varepsilon_{22}^* - \varepsilon_{11}^*)D^* \quad [29]$$

Furthermore, for the degree of anisotropy it follows that,

$$R = \frac{\varepsilon_1 - \varepsilon_2}{3\varepsilon} = \frac{1}{2} \sum_{i,j} (3g_{ij33} - \delta_{ij}) q_{ij}; \quad q_{ij} = \frac{\varepsilon_{ij}}{3\varepsilon} \quad [30]$$

where the q_{ij} are the squares of the direction cosines of the transition moment direction with respect to the x_i axes in the case of a pure polarized transition. For mixed absorption bands the q_{ij} are a measure of mixing. If the molecule-fixed coordinate system is arbitrarily chosen, nondiagonal elements occur in eqn [30]. The dipole strength is given by

$$D_k^A = \frac{12}{B} \int \frac{\varepsilon_k(\vec{v})}{\vec{v}} d\vec{v} = 3 \sum_{i,j} g_{ij33} D_{ij}^{NK} \quad [31]$$

$k = 1, 2$ and with $g_{ij33} = \frac{1}{3} \delta_{ij}$ follows $D^{NK} = \sum_i D_{ii}^{NK}$ for an isotropic solution. The transition moment tensor

$$D_{ij}^{NK} = \frac{4}{B} \int \frac{\varepsilon_{ij}(\vec{v})}{\vec{v}} d\vec{v} \quad [32]$$

can be calculated from the coordinates of the absorption tensor (eqn [32]).

The Tensor Coordinates of the CD Tensor $\Delta\varepsilon_{ij}^*$

The meaning of the diagonal elements of the tensor (eqns [18] and [36]) can be visualized according to **Figure 4**. $\Delta\varepsilon_{33}^*$ can be obtained by either calculating a mean value of three CD measurements for completely oriented molecules with light beams polarized parallel to the three planes, schematically represented in **Figure 4**, or one CD measurement with an ensemble of molecules in a uniaxial system with $S^* = 1$ or a system with at least a C_3 symmetry axis with a light beam propagating parallel to the optical axis or the C_3 symmetry axis. The coordinates $\Delta\varepsilon_{11}^*$ and $\Delta\varepsilon_{22}^*$ have to be evaluated from the temperature-dependent $\Delta\varepsilon^A(T)$ and $\Delta\varepsilon$. For a direct measurement analogous to that of $\Delta\varepsilon_{33}^*$, a new orientational distribution is needed in which there is a symmetric rotational distribution about either the x_1^* or the x_2^* axis. However, this procedure is nothing more than changing the numbering of the axes, because only that coordinate $\Delta\varepsilon_{ii}^*$ can be measured directly about which the orientational distribution possesses a rotationally symmetric distribution.

The $\Delta\varepsilon_{ii}^*$ can also be different in sign and thus one may say that by 'looking' at the molecule from different directions one 'sees' $\Delta\varepsilon_{ii}^*$ with different signs. Changing the line of sight, the now observed $\Delta\varepsilon_{ii}^*$ varies strongly and can also change its signs. One might loosely interpret this as 'seeing' the chirality of the molecule from different directions. This measurement must be done under conditions given in **Figure 4**.

The Molecular Description of the CD and the Absorption Tensor

The Equations for Molecules in an Orientated State

From semiclassical or quantum field theory, the rotational strength R_{ij}^{NnKk} for a transition from the electronic ground state N with the vibrational state n to the electronic excited state K with the vibrational state k , that is

Figure 4 Schematic representation of the measurement of $\Delta\varepsilon_{33}^*$.

$|Nn\rangle \rightarrow |Kk\rangle$, follows from the development of Kuball and co-workers:

$$R_{ij}^{NnKk} = \frac{1}{4} \sum_{r,s} \langle \mu_r \rangle_{NnKk} \langle \epsilon_{rsi} \rangle_{KkNn} + \epsilon_{rsj} \langle C_{si} \rangle_{KkNn} \quad [33]$$

The tensor $\langle C_{sj} \rangle_{KkNn}$ can be decomposed into a symmetric and antisymmetric part, the magnetic dipole and the electric quadrupole moment:

$$\langle C_{sj} \rangle_{KkNn} = -i \sum_r \epsilon_{sjr} \langle m_r \rangle_{KkNn} - \frac{\omega_{KkNn}}{c} \langle Q_{sj} \rangle_{KkNn} \quad [34]$$

$$\begin{aligned} \mu_i &= -e \sum_v x_{iv}; \quad Q_{ij} = -\frac{1}{2} e \sum_v x_{iv} x_{jv}; \\ m_r &= -\frac{e}{2mc} \sum_v \sum_{i,j} \epsilon_{rij} x_{iv} p_{jv} \end{aligned} \quad [35]$$

$\langle \mu_r \rangle_{NnKk}$ and $\langle m_r \rangle_{KkNn}$ represent the electric and the magnetic dipole transition moment, respectively, $\langle Q_{sj} \rangle_{KkNn}$ is the electric quadrupole transition moment. $-e$ is the charge, m the mass of the electron. $\sum_v$ means the sum over all electrons. Operators depending on the dynamic variables of the nuclei are omitted because they do not contribute to the effect in the approximation used. ϵ_{ijk} is the Levi-Civita tensor. $\epsilon_{123} = \epsilon_{312} = \epsilon_{231} = 1$, $\epsilon_{132} = \epsilon_{213} = \epsilon_{321} = -1$; all other tensor coordinates ϵ_{ijk} are equal to zero. With the rotational strength tensor R_{ij}^{NnKk} (eqn [33]) and the spectral function $G^{NnKk}(\bar{\nu})$ of the vibronic transition $|Nn\rangle \rightarrow |Kk\rangle$, the CD tensor $\Delta\epsilon_{ij}$ for an oriented molecule can be expressed as

$$\begin{aligned} \Delta\epsilon_{ij} &= B\bar{\nu} \sum_n \sum_{Kk} R_{ij}^{NnKk} G^{NnKk}(\bar{\nu}) \\ B &= \frac{32\pi^3 N_A}{10^3 hc \ln 10} \end{aligned} \quad [36]$$

N_A is the Avogadro constant and c is the velocity of light. The absorption of light by an oriented molecule requires knowledge of the electric dipole transition moment tensor (dipole strength)

$$D_{ij}^{NnKk} = \langle \mu_i \rangle_{NnKk} \langle \mu_j \rangle_{KkNn} \quad [37]$$

and the corresponding absorption tensor ϵ_{ij}

$$\epsilon_{ij} = \frac{1}{4} B\bar{\nu} \sum_n \sum_{Kk} D_{ij}^{NnKk} F^{NnKk}(\bar{\nu}) \quad [38]$$

$F^{NnKk}(\bar{\nu})$ is the spectral function for the absorption band of the vibronic transition $|Nn\rangle \rightarrow |Kk\rangle$ which, in the approximation that is used here, is equal to $G^{NnKk}(\bar{\nu})$.

The $\Delta\epsilon_{ij}$ term can be decomposed into an electric dipole/magnetic dipole and an electric dipole/electric

quadrupole contribution:

$$\Delta\epsilon_{ij}(\bar{\nu}) = \Delta\epsilon_{ij}^{\mu m}(\bar{\nu}) + \Delta\epsilon_{ij}^{\mu Q}(\bar{\nu}) \quad [39]$$

The decomposition is, except for special circumstances, origin dependent. From the diagonal elements $\Delta\epsilon_{ii}$ the quantities $\Delta_i(\bar{\nu})$ are defined by

$$\Delta_i(\bar{\nu}) = \frac{1}{2} [\Delta\epsilon_{11}(\bar{\nu}) - \Delta\epsilon_{22}(\bar{\nu}) - \Delta\epsilon_{33}(\bar{\nu})] \quad [40]$$

and cyclic permutation of the indices 1, 2, 3 can be calculated. The $\Delta_i(\bar{\nu})$ terms yield information about the electric dipole ($\langle \mu_i \rangle_{NnKk}$), magnetic dipole ($\langle m_i \rangle_{KkNn}$), and electric quadrupole ($\langle Q_{ij} \rangle_{KkNn}$) transition moments:

$$\begin{aligned} \Delta_i(\bar{\nu}) &= -\frac{1}{2} B\bar{\nu} \sum_n \sum_{Kk} \text{Im} \{ \langle \mu_i \rangle_{NnKk} \langle m_i \rangle_{KkNn} \} \\ &\quad \times G^{NnKk}(\bar{\nu}) + \Delta\epsilon_{ii}^{\mu Q}(\bar{\nu}) \end{aligned} \quad [41]$$

The decomposition of R_{ii}^{NK} corresponding to eqn [39] yields

$$R_{11}^{\mu m} = \text{Im} \{ \langle \mu_2 \rangle_{NK} \langle m_2 \rangle_{KN} + \langle \mu_3 \rangle_{NK} \langle m_3 \rangle_{KN} \} \quad [42]$$

$$R_{11}^{\mu Q} = -\langle \mu_2 \rangle_{NK} \langle Q_{31} \rangle_{KN} + \langle \mu_3 \rangle_{NK} \langle Q_{21} \rangle_{KN} \quad [43]$$

by integration over the absorption band. R_{22}^{NK} and R_{33}^{NK} can be obtained by cyclic permutation of the indices. The terms $\langle \mu_i \rangle_{NK}$, $\langle m_i \rangle_{KN}$ and $\langle Q_{ij} \rangle_{KN}$ are the electric dipole magnetic dipole and electric quadrupole transition moments for the 0–0 electronic transition $|N\rangle \rightarrow |K\rangle$. By integration of eqns [40 and 41], wavenumber-independent quantities Δ_i can be obtained with the tensors of rotation given by eqns [44] and [45] and cyclic permutation of the indices 1, 2, 3:

$$\Delta_1 = \frac{1}{2} [R_{11}^{NK} - R_{22}^{NK} - R_{33}^{NK}] \quad [44]$$

$$\Delta_i = -\frac{1}{2} \text{Im} \{ \langle \mu_i \rangle_{NK} \langle m_i \rangle_{KN} \} + R_{ii}^{\mu Q} \quad [45]$$

Vibronic Coupling in ACD Spectroscopy

Forbidden electric dipole transitions or allowed magnetic dipole transitions possess no or nearly no intensity of absorption in a spectrum. There are a number of different mechanisms by which a transition can gain intensity. One mechanism is the coupling of an electronic transition to the nuclear motions. By the weak dependence of the state functions $|Nn\rangle$, $|Kk\rangle$ on the nuclear coordinates, electronic states within the molecules are coupled. The transition moment of the forbidden transition $|N\rangle \rightarrow |K\rangle$ increases, as normally described, by borrowing intensity from other allowed electronic transitions via normal vibrations, that is the variation of the

normal coordinates. Within the adiabatic approximation, the coordinates of the absorption tensor ε_{ii}^* are intensified by the Herzberg–Teller mechanism via different normal vibrations which—depending on the irreducible representation to which the normal coordinate belongs—couple transitions with different transition moment directions. This can be demonstrated experimentally by measuring a frequency-dependent degree of anisotropy (eqn [30]). With the Herzberg–Teller method the intensification of $\Delta\varepsilon^A$ (eqn [46]) follows from Kuball and co-workers:

$$\begin{aligned} \Delta\varepsilon^A(\bar{\nu}) = B\bar{\nu} \sum_{ij} g_{ij33} & \left(R_{ij}^{NK} G^{NK}(\bar{\nu}) \right. \\ & + \sum_{\mu} R_{ij}^{NK,\mu} G^{NK,\mu}(\bar{\nu}) + \sum_{\mu,\nu} \left[R(1)_{ij}^{NK,\mu\nu} G_1^{NK,\mu\nu}(\bar{\nu}) \right. \\ & \left. \left. + R(2)_{ij}^{NK,\mu\nu} G_2^{NK,\mu\nu}(\bar{\nu}) \right] \right) \end{aligned} \quad [46]$$

R_{ij}^{NK} gives the contribution of the 0–0 transition to the CD band. The coefficients $R_{ij}^{NK,\mu}$, $R(1)_{ij}^{NK,\mu\nu}$ and $R(2)_{ij}^{NK,\mu\nu}$ determine the size of the intensity borrowing via the μ th and ν th vibrations from other electric dipole-allowed transitions with a corresponding transition moment direction. The frequency dependence of the progressions $G^{NK}(\bar{\nu})$, $G^{NK,\mu}(\bar{\nu})$, $G_1^{NK,\mu\nu}(\bar{\nu})$, and $G_2^{NK,\mu\nu}(\bar{\nu})$ are described by

$$G^{NK}(\bar{\nu}) = \sum_{n,k} |\langle n|k \rangle|^2 G^{NnKk}(\bar{\nu}) \quad [47]$$

$$G^{NK,\mu}(\bar{\nu}) = \sum_{n,k} \langle n|k \rangle \langle k|Q_\mu|n \rangle G^{NnKk}(\bar{\nu}) \quad [48]$$

$$G_1^{NK,\mu\nu}(\bar{\nu}) = \sum_{n,k} \langle n|k \rangle \langle k|Q_\mu Q_\nu|n \rangle G^{NnKk}(\bar{\nu}) \quad [49]$$

$$G_2^{NK,\mu\nu}(\bar{\nu}) = \sum_{n,k} \langle n|Q_\mu|k \rangle \langle k|Q_\nu|n \rangle G^{NnKk}(\bar{\nu}) \quad [50]$$

This means analogously to the UV absorption, each CD tensor coordinate $\Delta\varepsilon_{ii}^*$ is intensified by normal modes of different irreducible representations by a different

amount, that is each $\Delta\varepsilon_{ii}^*$ ($i=1,2,3$) borrows intensity from other electronic transitions of suitable symmetry (eqns [47–50]).

Because of the importance of intensity borrowing, a forbidden electric and magnetic dipole transition of a compound of symmetry D_2 will be analysed as an example. For the transition $|N\rangle \rightarrow |K\rangle$ between an electronic and vibrational ground and an electronic and vibrational excited state $A \rightarrow A$, only the coefficient $R(2)_{ij}^{NK,\mu\nu}$ in eqn [46] is different from zero. With eqn [50], the frequency dependence of the CD and ACD is determined by a progression starting on false origins of one vibration $\mu = \nu = 1, 2 \dots$ of an irreducible representation b_i ($i = 1, 2, 3$):

$$\bar{\nu}_k = \bar{\nu}_{00} + \bar{\nu}_{0\mu}(b_i) + n_k \bar{\nu}_0(a) \quad [51]$$

$n_k = 0, 1, 2 \dots$ are the quantum numbers for the k^{th} excited state of the involved totally symmetric vibration with the wavenumber $\bar{\nu}_0(a)$. $\bar{\nu}_k$ is the wavenumber for the $(k+1)^{\text{th}}$ band of the progression. The false origin is $\bar{\nu}_{00} + \bar{\nu}_{0\mu}(b_i)$ and every vibration of the irreducible representation b_i can cause intensity borrowing from an allowed electric dipole transition $A \rightarrow B_i$. The coupling scheme (Figure 5) for an $A \rightarrow B_i$ transition contributes with four terms. The intensity borrowing for the corresponding UV band is achieved by the same progressions (eqn [51]). The transition moment direction of the progressions is determined by the transition moment direction of the coupled electronic transitions $A \rightarrow B_i$. For the $A \rightarrow A$ transition, $\Delta\varepsilon_{11}$, ε_{33} and ε_{22} borrow intensity via vibrations of irreducible representation b_1 and b_2 . $\Delta\varepsilon_{22}$, ε_{11} and ε_{33} borrow the intensity via vibrations of symmetry b_3 and b_1 whereas $\Delta\varepsilon_{33}$, ε_{11} and ε_{22} gain the intensity from the coupling with b_3 and b_2 .

For each chromophore, the reduced CD spectra, the tensor coordinates $\Delta\varepsilon_{ii}$ and the reduced UV spectra, the tensor coordinates ε_{ii} gain intensity (Figure 6(a) and Figure 6(b)) by a special amount of coupling. By substituting the molecule in the neighbourhood of this chromophore, another coupling is achieved and the reduced spectra $\Delta\varepsilon_{11}$, $\Delta\varepsilon_{22}$, $\Delta\varepsilon_{33}$ as well as ε_{11} , ε_{22} , ε_{33} change. Thus, in both cases, $\Delta\varepsilon$, $\Delta\varepsilon^A$, ε and R are different.

Figure 5 Coupling scheme for intensity borrowing of the circular dichroism and absorption tensor coordinates of a forbidden $A \rightarrow A$ transition via the coefficient $R(2)_{ij}^{NK,\mu\nu}$ with one vibration b_1 from an allowed electric (—) and magnetic (---) dipole transition of $A \rightarrow B_1$. Quadrupole contributions are neglected for this discussion.

Figure 6 Calculated UV (left) and CD (right) spectra of the A→A transition for a molecule of symmetry D_2 for two different strength of vibronic coupling. The intensity of the vibrational progressions is changed from $\epsilon_{11} : \epsilon_{22} : \epsilon_{33} = 3 : 1 : 1$ (a left) to $\epsilon_{11} : \epsilon_{22} : \epsilon_{33} = 1 : 2 : 2$ (b): $\Delta\epsilon_{11}(\bar{\nu})$, $\epsilon_{11}(\bar{\nu})$ (—), $\Delta\epsilon_{22}(1)$, $\epsilon_{22}(\bar{\nu})$ (---), and $\Delta\epsilon_{33}(\bar{\nu})$, $\epsilon_{33}(A)$ (.....). The UV spectra ϵ (—) and the degree of anisotropy R (---), (c, left), the CD spectra $\Delta\epsilon$ (.....) and ACD spectra $\Delta\epsilon^A$ (---) (c, right) are given for the cases shown in (a) and (b). (●) intensity ratio $\epsilon_{11} : \epsilon_{22} : \epsilon_{33} = 3 : 1 : 1$; (■) intensity ratio $\epsilon_{11} : \epsilon_{22} : \epsilon_{33} = 1 : 2 : 2$. R and $\Delta\epsilon^A$ have been calculated for the order parameter $S^* = 0.460$ and $D^* = 0.121$ where D^* is calculated from Luckhurst's relation $D^* = F(S^*, \delta)$ with $\delta = 0.5$. According to eqn [51] the assumed 0–0 transition and false origins are $\bar{\nu}_{00} = 37\,100\text{ cm}^{-1}$; $\bar{\nu}_{01}(b_1) = 1100\text{ cm}^{-1}$; $\bar{\nu}_{02}(b_2) = 560\text{ cm}^{-1}$; $\bar{\nu}_{03}(b_3) = 430\text{ cm}^{-1}$; $\bar{\nu}_0(a) = 120\text{ cm}^{-1}$; the intensity ratio within the progressions is chosen equally for b_1 , b_2 , b_3 : 1 : 6 : 10 : 8 : 6 : 4 : 1.

With this simple model a sign change in $\Delta\epsilon$ and possibly also in $\Delta\epsilon^A$ can be obtained without changing the absolute configuration, thus the sector or helicity rules for this chromophore break down, because the sector rule is now applied to the CD of vibrational progression for which the rule was not developed. Applying the rule to measurements in isotropic solution, one has to presuppose that the same progression determines $\Delta\epsilon$ for both compounds. From ACD spectroscopy each tensor

coordinate $\Delta\epsilon_{ii}$ is obtained directly. This means that the sector rules or helicity rules can always be applied to that $\Delta\epsilon_{ii}$ for which the rule has been developed.

Application of ACD and Polarized UV Spectroscopy

In addition to the analytical application of the ACD spectroscopy as a fingerprint technique, structural

differences far from the chromophore can also be detected. A complete analysis of the ACD, the CD, the UV and the polarized UV spectra requires the order tensor or at least an estimation of the order parameters. The variation of $\Delta\epsilon^A$ with temperature for an $n\pi^*$ transition of androst-4,17-dien-3-one ([1]; **Figure 7**) and the knowledge of g_{ii33}^* from ^2H NMR allows the calculation of $\Delta\epsilon_{ii}^*$ with respect to the principal axis of the order tensor. The tensor coordinates $\Delta\epsilon_{ii}^*$ have different signs and are shifted with respect to each other, which indicates the vibronic effect of intensity borrowing. The UV spectrum of [1] as well as the coordinates $\Delta\epsilon_{ii}^*$ have a low spectral resolution in comparison to the CD spectrum $\Delta\epsilon$. The different signs of $\Delta\epsilon_{ii}^*(\tilde{\nu})$ and their shifts against each other 'burn holes' into the spectrum calculated from eqn [1]. Thus as often found in CD spectroscopy, an apparent high spectral resolution of the CD spectrum is obtained in contrast to the UV spectrum.

As a second example, $\Delta\epsilon^A$ for a uniformly polarized charge transfer transition of 1,4-bis(*R*)-1-phenylethyl-amino)-9,10-anthraquinone [2] is shown in **Figure 8**. There is no vibronic coupling, and therefore no difference in the frequency dependence of the tensor coordinates. Furthermore, the tensor coordinate $\Delta\epsilon_{\vec{a}} \approx 0$ because the transition is polarized parallel to the x_3^*

direction (long axis of the anthraquinone skeleton). This indicates that for [2] the x_3^* axis is approximately a principal axis of the CD tensor. Of interest, but not shown for [2], is the large contribution of the electric dipole/electric quadrupole term (eqn [39]) to $\Delta\epsilon_{ii}^*$ in the wavenumber region below $25\,000\text{ cm}^{-1}$.

With the steroid 3-methyl-3 α -5 α -3,3',4',5'-tetrahydrobenzo[2,3]cholest-2-en-1-one [3] and its diastereomer [4], the breakdown of a helicity rule was demonstrated by Frelek and co-workers (**Figure 9**). From X-ray analysis it is known that the helicity of the enone chromophore is opposite in sign in [3] and [4], and thus the fact that $\Delta\epsilon < 0$ in both cases contradicts the helicity rule for cisoid enones either for [3] or for [4]. From ACD spectroscopy follows that the enhancement of the $\Delta\epsilon_{ii}^*$ by vibronic coupling for [4] yields a sign change of $\Delta\epsilon$ without change of the absolute configuration of [4]. This is the first example where this effect has been proven.

At the end of the section on applications one must point out that it is impossible, at present, to obtain experimentally the CD $\Delta\epsilon_{ij}$ or the rotational strength tensor R_{ij}^{Nnkk} with respect to their own principal axes. For a molecule of D_2 symmetry, the orientation of the principal axes of R_{ij}^{Nnkk} is symmetry determined.

Figure 7 $\Delta\epsilon$ (—) ($T = 75^\circ\text{C}$) and temperature-dependent $\Delta\epsilon^A$ (from above T ($^\circ\text{C}$) = 31.2–64.0) (left) and the tensor coordinates $\Delta\epsilon_{11}^*$ (■), $\Delta\epsilon_{22}^*$ (●), $\Delta\epsilon_{33}^*$ (▲) and $\Delta\epsilon_{11}^* + \Delta\epsilon_{22}^*$ (▼) (right) of androst-4,17-dien-3-one [1] in the 'nematic' liquid crystal phase ZLI-1695 (Merck).

Figure 8 $\Delta\epsilon$ (O) ($T=75^\circ\text{C}$) and temperature-dependent $\Delta\epsilon^A$ (from above $T(^{\circ}\text{C})=28\text{--}68$) of 1,4-bis(*R*)-1-phenylethylamino-9,10-anthraquinone [2] (left) and the tensor coordinates $\Delta\epsilon_{11}^*$ (---), $\Delta\epsilon_{22}^*$ (....), and $\Delta\epsilon_{33}^*$ (—) (right) of the charge transfer transition in the 'nematic' liquid crystal phase ZLI-1695 (Merck).

Isotropic Phases with Suprastructural Phase Chirality

With ACD and CD spectroscopy, information can be obtained about suprastructural chirality of isotropic phases, for example cubic phases with suprastructural chirality. There is no interference with linear effects and thus $\Delta\epsilon$ and $\Delta\epsilon^A$ can easily be measured. A well-known example is crystalline NaClO_3 . Another known example is that of liquid crystalline blue phases (O^2 , O^8). Both with light in the region where λ is of the order of the periodicity within the phase and with wavelengths very different from the periodicity, a CD spectrum is obtained from which a detailed analysis of the phase structure has been derived, for example by Hornreich and colleagues.

Anisotropic Phases with Suprastructural Phase Chirality

Chiral Anisotropic Phases of Chiral Molecules

Anisotropic phases are often stabilized by chiral structures. Before discussing phenomena presented by such structures, the question must be answered of how

chirality information about molecular chirality and suprastructural phase chirality is to be obtained from chirality measurements of anisotropic phases. Ruch and Schönhofer defined the notion of chirality measurement for an isotropic system: 'a chirality measurement of a property is a measurement with an ensemble of non-oriented molecules, and this measurement leads for enantiomers to a result of the same value but with an opposite sign'. Extending this definition to anisotropic systems one might say that 'a chirality measurement of a property with an ensemble of oriented molecules, that is the anisotropic phase, is a measurement with an ensemble of non-oriented supermolecules – that is an ensemble of "anisotropic phases" – and this measurement leads for an enantiomer of such an ensemble of supermolecules to a result of the same value but with an opposite sign'. Furthermore, for oriented molecules the anisotropy of chirality measurements has been demonstrated with ACD spectroscopy. In analogy to molecular properties, one must expect to find an anisotropy for any chirality measurement of a chiral anisotropic phase. Considering the chiral anisotropic phase as a supermolecule, as done before, a chirality measurement with CD spectroscopy is a measurement with the phase

Figure 9 UV spectra ($T=75^\circ\text{C}$), temperature dependent degree of anisotropy ($T(^{\circ}\text{C})=28\text{--}67.5$) (left), $\Delta\epsilon$ ($T=75^\circ\text{C}$) and temperature dependent $\Delta\epsilon^A$ ($T(^{\circ}\text{C})=28\text{--}67.5$) (right) of the cisoid enones 3-methyl-3 α ,5 α ,3,3',4',5'-tetrahydrobenzo[2,3]cholest-2-en-1-one [3] (above) and its 3 β -diastereomer [4] (below) in the 'nematic' liquid crystal phase ZLI-1695 (Merck).

rotated about the direction of the propagating light beam analogously to **Figure 4**. Do such definitions hold in general? One question arises immediately from the knowledge that, for oriented achiral molecules of symmetry C_n , C_{2v} , D_{2d} and S_4 with suitable achiral positional and orientational order, nondiagonal elements of the rotational strength tensor $R_{ij}^{N\mu}$ can lead to a CD effect. This effect has been shown by Hobden using optical rotation measurements with crystals (e.g. $\bar{4}2m$ or $\bar{4}$) without enantiomorphism. Is this an effect of chirality? Not really, because the CD is zero if this definition of a chirality measurement/observation is applied.

For a homogeneous sample, the phenomenological constants a_2 and b_2 are responsible for the circular effects (eqns [9]–[13]). But what does 'homogeneous' mean in a sample possessing positional and orientational order? Whether a phase represents a homogeneous or an inhomogeneous sample depends on the method used for

the analysis. For an optical measurement, as for example with a cholesteric phase or a smectic C^* phase, this depends on the chosen wavelength of the light, that is on whether the wavelength is close to or far from the dimension of the periodicity of the phase. In the first case eqns [9]–[13] are not valid because no 'internal reflection', originating from a periodicity of the inhomogeneity, has been taken into account. Berreman's theory and its extension for samples with very small pitch are discussed by Oldano and colleagues. The optical constants a_1 , a_3 , b_1 and b_3 that are responsible for local linear birefringence and dichroism are then according to the de Vries model the main origin for optical effects caused by the chirality of the sample.

Eqns [9]–[13] integrated over the periodicity of a helical phase can also be applied to describe a circular dichroism often termed 'liquid crystal induced circular dichroism' (LCICD) in cases where the pitch $p \gg \lambda$ or

$p \ll \lambda$. The CD originates from the helical arrangement of the absorbing molecules owing to their orientation in an anisotropic sample. The molecules and thus the chromophores dissolved in the anisotropic helical phase that are responsible for the CD can be chiral or even achiral. The LCICD is always magnitudes larger than the molecular CD in isotropic or anisotropic systems without supramolecular chirality. LCICD is found, for example, in cholesteric and chiral smectic C* liquid crystalline phases as shown by Gray. The sign of the LCICD provides information about the handedness of the phase.

Comparatively few optical investigations of chiral structures in anisotropic phases are known for two reasons. First with CD spectrometers based on polarization modulation, an artificial CD is often measured because of incorrect superposition of linear and circular effects in the signal processing. Second, the method for the decomposition of a measured quantity into the chiral and achiral part is not well developed. In the case of small linear and circular effects it is sufficient to expand the exponential (eqn [11]) up to the first order. The linear approximation for $F(A')$ (eqn [9]) can be applied and the contributions of linear and circular effects are additive, as for example for polymer or liquid crystalline polymer films. By measuring the state of polarization as a function of the azimuth of the sample, the CD originating from a chiral structure in the films can be evaluated. The expansion is, in general, not appropriate, because the linear effects are three to five orders of magnitude larger than the circular effects.

Chiral Anisotropic Phases of Achiral Molecules

In inorganic salts such as NaClO_3 discussed earlier, or quartz, chiral structures are built up from achiral species. An interesting field has been opened by the analysis by Takezoe and colleagues of the so-called 'banana shaped' molecules, which build up chiral domains together with phase separation, although, as is generally believed, they consist of achiral molecules. The analysis of such chiral phases by CD or ACD spectroscopy opens up a new field for an analysis of suprastructural chirality.

Introduction

A chromatography-IR spectroscopy combination can be approached from two angles. The method can be seen as (i) a chromatograph with a specific IR-spectroscopic detector, to ensure selective detection or (ii) as an IR spectrometer preceded by a chromatographic device to provide samples of appropriate purity. In any case, the essence is a separation and subsequent identification of pure samples. Thus, a chromatography-IR spectroscopy combination is applicable to any analytical problem in which the components of a composite sample (mixture) are to be identified, and it can be expected that a chromatographic method can be applied successfully for separation and IR spectroscopy can give at least pieces of information for identification.

Before the introduction of FT-IR instruments, the spectroscopic measurement was always carried out off-line, separately from the chromatographic process, with the insertion of an often-tedious sample-preparation step, which limited the applicability. The multiplex and throughput advantages of FT-IR spectroscopy have significantly improved the sensitivity and reduced the time demand of IR-spectroscopic measurement, making it possible to perform chromatographic separation with simultaneous, on-line IR-spectroscopic detection and identification, opening up thereby an extremely wide field of application. The chromatographic methods that offer the possibility of on-line spectroscopic detection are gas chromatography (GC), high-performance liquid chromatography (HPLC) and supercritical-fluid chromatography (SFC). Thin-layer chromatography (TLC) can also be combined 'on-line' with IR spectroscopy insofar as spectra can be taken directly from the chromatographic plate.

Chromatographs and FT-IR spectrometers can be interfaced by two distinct approaches. In the first, the effluent from a chromatographic column is passed through a flowcell (often called 'light pipe' in GC/FT-IR) together with the chromatographic carrier, where infrared spectra are measured continuously. In the second approach the carrier is removed, the eluates are deposited on a suitable substrate (as such or isolated in a matrix), and the infrared measurements are made some time after deposition. Thus, when discussing the applications of GC/FT-IR, HPLC/FT-IR and SFC/FT-IR

techniques, flowcell techniques and deposition techniques will be treated separately. TLC/FT-IR can be accomplished *in situ* or by transferring the eluates from the plate to an IR-transparent material, but these techniques will be discussed only briefly in a single section.

GC/FT-IR – FlowCell (Light Pipe) Approach

This method is applicable to any sample that can be evaporated in the injector of the GC, separated into its components on the column, and which, mixed with the carrier gas, remains in the gas phase and suffers no decomposition in the heated transfer line and the flowcell (light pipe) of the GC/FT-IR interface. If this is not the case, HPLC or SFC should be used for separation. However, this restriction still leaves an extremely wide choice of possible applications, of which only some examples are discussed below.

Industrial Applications

In industrial processes starting materials, intermediates and end products are regularly analysed, in which GC/FT-IR may have its due share. For example, solvents are recycled after distillation or other purification steps. The purity of solvents is checked before recycling by gas chromatography, where eventual impurities, once known, are identified on the basis of retention times. In the case of unknown impurities GC/FT-IR or GC/MS methods must be used for identification, of which the former is particularly useful if aromatic isomers are to be distinguished. Another important area is monitoring reactions like catalytic oxidation or polymerization.

Petrochemistry

The distinction of aliphatic isomers and homologues in crude oil and gasoline fractions by IR spectroscopy is a hard task. However, the method is very powerful if the identification of aromatic compounds in oil fractions is required. The discrimination ability of IR spectroscopy is also high when the substitutional isomers of polycyclic aromatic hydrocarbons (PAH) are to be identified. The method is also applicable in the analysis of antioxidants used in oils and fuels.

Pollutants in the Environment

One of the first applications of GC/FT-IR was, in 1979, the identification of alkyl-9-fluorenones in diesel exhaust particulate extracts. Some years later in the EPA laboratory of Athens, GA, USA and then in the EPA laboratory of Las Vegas, GC/FT-IR was applied to identify toxic substances in environmental-sample extracts. In the latter laboratory, the minimum identifiable quantities of 30 priority pollutants and 25 other environmental contaminants were determined. The method was shown to be applicable for the analysis of hazardous waste and industrial wastewater extracts. The gas-phase spectra of 47 compounds of environmental importance were also taken, and their characteristic absorption frequencies and specific absorbances were published.

Important groups of pollutants are pesticides, fungicides and insecticides. Their toxicity has made it necessary to monitor their presence in the food chain, soil or water. Analytical and monitoring techniques first relied on the GC analysis of a limited number of target compounds. However, in the identification of other residues that were suspect but not among the preset target compounds, IR-spectroscopic information often proved to be vital. There are three problems making this analysis difficult: the large number of components, the presence of a number of conformers or isomers with widely varying degree of toxicity or biochemical activity, and the possibility of the formation of new degradation products. GC/FT-IR is suitable for tackling all the three, being particularly useful in the differentiation between isomers (often superior to MS) and in the identification of degradation products.

Of the other pollutants, polychloro-dibenzodioxins have attracted special attention, where a crucial point is the differentiation between isomers, since some of them are extremely poisonous. Of these compounds the vapour-phase IR spectra of 22 tetrachloro-dibenzodioxins (TCDDs) were taken to prove that the TCDD isomers have unique IR spectra. Indeed, spectra-structure correlations showed that each TCDD isomer has characteristic, individual asymmetric and symmetric COC stretching frequencies, on the basis of which they can be safely distinguished at low-microgram concentrations from other, less-toxic isomers.

GC/FT-IR can also be used to identify pesticide degradation products, including low-volatility pesticides and their residues in biological samples. For example, phenols and 2,4-dichlorophenoxyacetic acid derivatives were analysed in body fluids of humans exposed to pesticides. More recent topics of analysis are complex marine mixtures, nitrated polycyclic aromatic hydrocarbons in environmental samples, aromatic isomers in marine samples and fatty acid methyl esters in the marine environment.

Natural Products of Vegetable Origin (Flavours, Fragrances and Essential Oils)

Essential oils are complex mixtures for which conventional GC techniques (retention index) are insufficient for complete identification. The need for the information supplied by the infrared spectrum justifies here the use of GC/FT-IR. In a similar manner to pesticides, particular flavours are often associated with one of the possible several isomers or conformers.

For example, the essential oil of *Anthemis nobilis* L. is a mixture of terpenoids and saturated and unsaturated C₄ and C₅ acids esterified by saturated or unsaturated C₃ to C₆ alcohols. GC/MS with electron-impact ionization fails to distinguish the angelates and tiglates of unsaturated alcohols, whereas these geometric isomers have widely different characteristic frequencies in the infrared. The same holds for the distinction between crotonates and methacrylates or between linear and branched ethers. A further interesting example is the case of α -pinene and γ -terpinene with very similar MS but sufficiently specific IR spectra. GC/FT-IR has been used to analyse a number of other essential oils, like the flavour components in kiwi, peppermint oil, lemon oil or the essential oil extracted from celery seed. An analogous task was the identification of 43 components in the headspace of coffee samples.

Biomedical Applications

GC/FT-IR can be used in biomedicine to detect and identify medicaments, toxic compounds and narcotics as well as their metabolites in biological fluids (blood, urine, bile, etc.). Of course, samples must be pre-treated prior to GC/FT-IR analysis to have relatively clean extracts. The metabolic pathways of drugs or potential drugs can also be established by analysing biological fluids for the decomposition products. An interesting example is the metabolism of trifluoromethylethyl benzhydrol, an effective hepatic enzyme inducer. Many of its metabolites are polyhydroxy compounds, the isomers of which could be distinguished only by GC/FT-IR.

In toxicology it is very important to identify the product that is responsible for fatal poisoning. A GC/FT-IR method has been elaborated, e.g. for the identification of paraquat, a herbicide, and for the diagnosis of fatal poisoning due to the vapours of volatile solvents (acetone, diethyl ether, trichloroethylene, etc.) used by young drug addicts. In the analysis of narcotics and drugs of abuse (heroin, cannabis, LSD, cocaine, amphetamines, etc.) GC/FT-IR is essential in identifying the numerous isomers, and also applicable in the analysis of barbiturates or stimulants abused as drugs. By identifying impurities, the 'fingerprint' of drugs can be determined, which can serve as a basis of checking the geographical origin of drugs of abuse.

Polymer Analysis

GC/FT-IR is highly applicable in the study of polymers. On heating the sample the polymer is degassed or (partly or completely) decomposed, and thus gases are produced. Pyrolysis can be used to determine the structure of polymers on the basis of the resulting fragments. An example is the pyrolytic study of polybutadiene in which a number of monosubstituted vinyl compounds can be distinguished on the basis of their characteristic C–H out-of-plane frequencies. A similar approach was used in the analysis of elastomers applied in the automobile industry and of epoxy–phenolic resins. Pyrolysis-GC/FT-IR is applicable in the study of the thermal degradation of thermoresistant amide, imide and diimide polymers. Although not directly related to polymer chemistry, it is noted that substructure components of various aquatic humic substances can also be identified by this method. Thermogravimetric analysis (TGA) can also be combined with GC/FT-IR: an example is a study of the decomposition of ethylene–vinyl acetate copolymers by TGA/GC/FT-IR analysis.

Miscellaneous Applications

GC/FT-IR can be used for amino acid profiling with *tert*-butyldimethylsilyl derivatization, for the investigation of food-packaging materials, the analysis of biologically active wheat straw extracts with allopathic activity, that of *cis*- and *trans*-octadecanoic acids in margarines and of sugar units in disaccharides, for the identification of small molecular migrants extracted from γ -irradiated plastic laminates or the radiolysis products of γ -irradiated medazepam solution.

GC/FT-IR – Subambient Solute Trapping (Direct-Deposition) Approach

In this direct-deposition (DD) technique, the eluates are deposited on a moving ZnSe window cooled by liquid nitrogen, and the spectra are measured continuously, a short time after deposition. The resulting spectra are very different from gas-phase spectra, being more similar to spectra of samples prepared as a KBr disk or Nujol mull; thus they may be searched against standard condensed-phase reference libraries, as was shown for the example of barbiturates (barbital, apobarbital, buta-barbital, phenobarbital). This is an advantage over matrix isolation (MI) detection (see below). Detection limits for on-line measurements are almost two orders of magnitude lower than in the case of a flowcell interface, and the limits can be pushed down by post-run spectrum recording, which is easy to perform with DD interfaces.

An interesting application of this technique was the analysis of β -agonists in cattle. These compounds are a

group of *N*-phenylethanolamines illegally used in the treatment of veal and cattle. In this study tissue samples were analysed for the presence of clenbuterol, mabuterol and salbutamol, all of which were trimethylsilylated before analysis. The limit of detection was ~ 1 to $2.5 \text{ ng } \mu\text{L}^{-1}$. Another important application is in forensic toxicology, where the compound must be identified by at least two independent methods. Here, GC/DD/FT-IR is a good second technique in addition to GC/MS. A characteristic application is the distinction between amphetamines and metamphetamines in post-mortem analyses.

GC/FT-IR – Matrix-Isolation (MI) Approach

The isolation and structure elucidation of complex mixtures require high-resolution chromatographic separation coupled with advanced spectroscopic techniques. This is offered by matrix isolation (MI), based on mixing the eluate with a noble gas (e.g. argon) and depositing the mixture on a metal surface cooled to a temperature of 10 K, where the eluate molecules are trapped in a matrix of the noble gas. The analysis of essential oils may require such an approach. For instance, peppermint oil contains (–)-menthol as the main component causing a cooling sensation, whereas other isomers (neomenthol, isomenthol and neoisomenthol), though structurally similar, have no such effect. Mass spectrometry is unable to differentiate between these isomers; however, the MI/FT-IR spectra show characteristic differences (see **Figure 1**). Soya bean oil is an important vegetable oil, in which the presence of unsaturated fatty acids causes instability. GC/MI/FT-IR can be applied successfully to determine the presence and structure of any unsaturated

Figure 1 MI/FT-IR spectra (fingerprint region) of (a) menthol, (b) neomenthol, (c) isomenthol and (d) neoisomenthol, 25 ng each. Reproduced with permission of the Society for Applied Spectroscopy from Coleman III WM and Gordon BM (1989) Examinations of the matrix isolation infrared spectra of organic compounds: Part XIII. *Applied Spectroscopy* 43: 303.

species. In essential oils used for aroma, flavour and fragrance purposes, stereochemical conformations and configurations play an important role in sensory responses. For instance, geraniol and nerol in coriander oil differ only in the *trans* vs. *cis* conformation of the double bond, which is readily distinguished on the basis of the MI/FT-IR spectrum.

Due to the low-nanogram sensitivity of the GC/MI/FT-IR technique, minor components of natural essential oils can be detected and safely identified on the basis of spectral differences due to positional isomers. Similarly to the light pipe approach, or even more so, this technique is fitted to the identification of the isomers of polycyclic aromatic hydrocarbons (PAH), e.g. in soil samples. Picogram levels of polychlorinated biphenyls and chlorinated dibenzo-*p*-dioxins can be determined as well as nitroresols in air-sample extracts.

HPLC/FT-IR – Flowcell Approach

The first flowcell experiment was reported in 1975, and some years later in 1979 Vidrine reviewed the most important points of this technique, limited at that time to size-exclusion chromatography (SEC). The use of flowcell methods with normal- and reversed-phase chromatographic separations has proven more difficult, since for a successful coupling the spectroscopic properties of the solvent system should meet some minimum requirements. In this respect deuterated solvents seemed to be promising, and numerous applications have been reported on normal-phase, flowcell HPLC/FT-IR, in which deuterated or halogenated solvents were used. Hydrocarbons, esters, ketones, phenols, amines and azarenes were easily separated and detected. To increase chromatographic performance, small amounts of polar modifiers can be added to the mobile phase without seriously affecting IR-detection ability. However, gradient elution, or traces of water, buffer or alcohol proved to be incompatible with the flowcell method. To overcome this problem, the aqueous effluent can be extracted with an IR-compatible solvent and the resulting solution measured in the flowcell.

Using microbore LC columns, a separation method was developed for a series of weakly basic cyclic and noncyclic secondary amines, which were identified as components of coal-derived solvents. As shown in another study, using normal HPLC on silica gel with Freon-113 elution, model mixtures of aliphatic and aromatic hydrocarbons and nonpolar constituents can be separated in coal-liquefaction process solvents. Encouraging results were obtained on both semipreparative (4.6 mm i.d.) and microbore (1 mm i.d.) columns. According to further reports, carbamate pesticides, polymer additives and solvent-refined coal were analysed, and the components of bergamot oil can be identified. GPC/FT-IR can be

used to detect components of cold-rolling oil and to analyse polymers, whereas SEC/FT-IR can be applied to the analysis of coal liquids and to improve detection and identification of proteins.

HPLC/FT-IR – Solvent-Elimination Approach

With the removal of the mobile phase, IR detection no longer restricts the selectivity of the chromatographic process through solvent-transparency requirements. Solvent elimination is more difficult with reversed-phase chromatography because of the presence of water. This problem can be overcome by extraction with organic solvent, and deposition of the organic solution in a known manner, or by a post-column reaction with 2,2-dimethoxypropane, converting water into methanol and acetone, which have sufficient volatility for the deposition technique.

In the first realization of solvent-elimination HPLC/FT-IR the solution eluting from the column is concentrated in a short heated tube, then passed dropwise onto a cup filled with KCl powder, held in a carousel. After the evaporation of solvent, the IR spectrum can be taken in diffuse reflection (DR). In another approach (called 'buffer memory') the effluent is deposited on a KBr plate as a narrow, continuous band, and IR spectra are measured in transmission. This method was illustrated for the example of polystyrene and Carbowax 6000. According to a third technique, using microbore columns, eluates are again deposited on KCl, and IR spectra are measured in DR. The performance was investigated on a test dye solution (Butter Yellow and Indophenol Blue), and on a mixture of nitrobenzene and 4-chloronitrobenzene.

It is worth noting that over the history of HPLC/FT-IR only a limited number of real applications have been reported in scientific papers, most of them dealing with improvements on the technique or investigations on its performance. Of the few applications, the analysis of chloropyrene isomers and congeners, organics in water and polymer-composition distribution can be mentioned.

SFC/FT-IR – Flowcell Approach

The development of SFC/FT-IR has closely paralleled that of HPLC/FT-IR. In both cases the first demonstration of the technique was the flowcell approach, and the solvent-elimination techniques (using transmission and diffuse-reflection arrangements) appeared slightly later. The flowcell approach in SFC appeared to be superior to the same in HPLC for two basic reasons: (i) the preferred SFC mobile phases transmit IR radiation over a larger frequency range than many HPLC solvents, and (ii) density programming in SFC poses fewer difficulties

in solvent subtraction than the solvent-gradient technique used in HPLC analysis.

The choice of a suitable mobile phase is subject to the following conditions: (i) minimum absorption in the mid-IR, (ii) adequate solvation of the molecules of interest in SFC, (iii) high solute diffusivities to permit high column efficiencies and (iv) a high degree of selectivity as a function of pressure variation. Whereas the most common candidate, supercritical carbon dioxide, fulfils many of these conditions, its polarity and solvent strength are only moderate. However, adding small amounts of more polar compounds to carbon dioxide may result in increase of solvent strength without substantially compromising IR measurement (although some authors are of different opinion). Still, even without modifiers, the absorption of carbon dioxide may cause problems, for instance in the identification of hydroxy compounds (the OH stretching region coincides with a strong carbon dioxide absorption band). Thus, some authors prefer using xenon as the mobile phase, which has no IR absorption.

The first demonstration of SFC/FT-IR coupling was reported in 1983 with the use of a wide-bore fused-silica capillary column, supercritical carbon dioxide and a flow-cell of 1 cm pathlength. With this setup, easily identifiable spectra can be obtained for 3 µg each of anisole, acetophenone and nitrobenzene.

An interesting application is the analysis of ultraviolet-curing inks and coatings. These formulations contain oligomers, a reactive diluent and a photoinitiator, where the oligomers are low- to medium-molecular weight multifunctional, unsaturated materials. SFC/FT-IR is an ideal method for their analysis, since it allows high-resolution separation of mixtures at low temperatures, while the components are readily identified on the basis of their characteristic IR spectra. This is shown, e.g. by the analysis of the volatile components of citrus oil and that of model steroid mixtures, pyrethrins (naturally occurring esters with insecticidal activity). Typical identification limits, as studied with caffeine as model, are in the 2 ng range. In a commercial preparation of pyrethrin extract, the six insecticidally active components were separated by SFC, since thermal degradation was observed when attempting GC separation. IR spectra of the components taken in the flowcell clearly reveal the structural differences between them. Practical applications of SFC/FT-IR include the determination of non-volatile compounds from microwaveable food packaging that may migrate into the heated food. Another application is the analysis of fibre finishes on fibre/textile matrices.

SFC/FT-IR – Solvent-Elimination Approach

In contrast to flowcell interfaces, solvent-elimination approaches lead to spectra free of solvent interferences.

Various sampling techniques are possible: the sample can be deposited on a flat ZnSe plate, on a smooth metallic substrate or a thin layer of powdered alkali halide salt, whereas the spectrum can be taken in conventional transmission, external-reflection or diffuse-reflection arrangement. In one of the first applications a synthetic mixture of three quinones was separated on a microbore column packed with silica, using a mobile phase of 5% methanol in supercritical carbon dioxide. The peaks were collected on a plate on which a layer of KCl powder was deposited, and then spectra were measured by a diffuse-reflection accessory. Test measurements on acenaphthene-quinone (AQ) showed later that conventional transmission spectra of samples on flat infrared-transmitting windows give the best compromise between high sensitivity, correct relative band intensities and adherence to the Lambert-Beer law.

A modern device is a real-time (on-line) SFC/FT-IR interface based on a commercial direct-J;deposition GC/FT-IR system, described by Norton and Griffiths, which allows spectra of subnanogram quantities of analytes to be measured over the complete mid-IR region. It is possible to get identifiable spectra from injections as low as 600 pg for strong IR absorbers and between 1 to 10 ng for weaker IR absorbers. The interface also allows for usage of polar modifiers in the mobile phase.

TLC/FT-IR

This combination can be approached in two ways: either the FT-IR measurement is performed *in situ*, directly on the TLC plate, or the analytes are transferred from the plate to an IR-transparent substrate prior to the FT-IR measurement. Interfaces for both methods are now commercially available. NIR and photoacoustic FT-IR detection have also been applied, although to a lesser extent, in the coupling of TLC with IR spectroscopy.

Conclusion

It is important to note that scientific papers or reviews are not the most appropriate sources of information on the application of chromatography-IR spectroscopy combinations. These techniques, like most of the techniques of instrumental analysis, are widely applied just as an analytical tool in research laboratories and in industry. Typical accounts of these applications are progress reports, technological prescriptions or patent applications, rather than scientific papers.

When considering the application of chromatography-IR spectroscopy combination techniques, three questions should be answered: (i) is the problem the analysis of a composite sample? (ii) can the sample be separated by a chromatographic method? (iii) is there a

chance that the IR spectrum of the components will help identification? If the answer is 'yes' to these questions, a chromatography-IR spectroscopy combination is a promising approach to the analytical problem.

Linking chromatographic separation methods with IR spectroscopic detection of separated components results in powerful chemical analysis tools. As with any hyphenated analysis method, combining mixture component separation with infrared spectroscopic detection provides capabilities that surpass those of the constituent techniques. Unlike conventional chromatography detectors, IR analysis provides detailed structural information regarding complex mixture components. In favourable cases, mixture components can be unequivocally identified based on their chromatographic retention times and IR spectra. The performance characteristics of chromatography-IR combinations are largely determined by the interface employed. The ideal chromatography-IR interface would link the two techniques without sacrificing the performance of either. In practice, instrument performance tradeoffs are unavoidable. A variety of interfaces have been developed in attempts to minimize these tradeoffs when gas chromatography, liquid chromatography, supercritical fluid chromatography, and thin layer chromatography are combined with IR spectroscopic detection.

Inherent in all chromatography-IR combinations is the need for rapid IR spectrum measurement. Fourier transform IR spectrophotometry (FT-IR) provides rapid scanning and is the preferred IR spectroscopic technique for detection of species separated by chromatographic methods. Instrumental requirements for chromatography-IR interfaces depend on many factors. In particular, the physical state of matter that must be analysed determines which spectroscopic sampling techniques can be employed. For example, gas chromatography detectors must provide a means of analysing flowing vapours. Liquid and supercritical fluid chromatography detection requires analysis of flowing liquids. IR detection of thin layer chromatography solutes presents the particularly difficult problem of analysing species adsorbed on infrared opaque substrates.

Chromatogram Generation

Regardless of the type of chromatography implemented or the specific chromatography-IR interface employed, separated mixture components are ultimately represented by a plot of detector response as a function of

separation time or migration distance. There are two common procedures for converting structure-specific IR spectroscopic information into chromatogram plots. The Gram-Schmidt vector orthogonalization method uses subtle variations in interferogram data acquired during FT-IR scans to detect solute elutions. The functional group chromatogram method is more computationally intensive and requires interferogram Fourier transformation and calculation of absorbance spectra, but can be used to elucidate mixture component structural features.

For Gram-Schmidt chromatogram generation, a portion of each acquired FT-IR interferogram is selected to represent a multidimensional vector. The number of interferogram data points used to form vectors determines the dimensionality of the vector space and thus the number of orthogonal axes needed to define the space. Vectors derived from interferograms obtained when no solute is present in the IR beam are similar and are confined to the same region of the vector space. By using the Gram-Schmidt orthogonalization method, a few of these background vectors are used to calculate orthogonal axes that are representative of the portion of the vector space in which background vectors are found. Chromatogram generation is accomplished by comparing the orientation of measured interferogram vectors with the background subspace. Interferograms acquired when solute is in the IR beam have vector components outside of the background subspace. The sum of vector residuals remaining after removing those components that lie in the background space are plotted as a function of elution time or migration distance to yield a chromatogram. Gram-Schmidt chromatogram intensity is therefore a measure of how much interferogram vectors differ from the background subspace, a quantity not necessarily related to IR absorbance. The signal-to-noise ratio of Gram-Schmidt generated chromatograms depends on the number of interferogram points used to define vectors, the number of orthogonal axes used to specify the background subspace, and the interferogram segment used to create vectors.

Functional group specific chromatograms are generated from chromatography-IR absorbance spectra by plotting the integrated absorbance within selected wavelength regions as a function of elution time or migration distance. Significantly more calculations are required to create functional group specific

chromatograms than to generate Gram–Schmidt chromatograms. However, functional group specific chromatograms provide much more information regarding separated species structures than Gram–Schmidt chromatograms. Typically, multiple wavelength regions are integrated to produce several functional group specific chromatograms. When separated species contain functionalities that absorb within a selected wavelength region, a peak representing the elution of this substance will appear in the chromatogram. Total IR absorbance chromatograms are generated by integrating spectra over the entire mid-infrared range (e.g. 4000–400 cm^{-1}). The total IR absorbance chromatogram contains peaks representing all infrared absorbing solutes.

Gas Chromatography-IR

The most commonly employed chromatography-IR combination is between gas chromatography (GC) and FT-IR. Interfaces for GC-IR can be categorized as either flow cell (light pipe) or solute trapping. Figure 1 illustrates the three GC-IR interfaces described in the following sections.

Light Pipe GC-IR

The first on-line GC-IR interface consisted of a heated flow-through gas cell or 'light pipe'. Simple and inexpensive light pipe interfaces constitute the most common method employed for combining gas chromatography with infrared spectrophotometry. In these combinations, IR radiation from an FT-IR source is directed through a light pipe, which is a glass tube with a gold-coated inner surface through which the gas chromatographic effluent flows. The light pipe contains no chromatographic stationary phase. Therefore, it does not

contribute to mixture component separation. In fact, the light pipe dead volume results in degradation of chromatographic resolution. To minimize chromatographic resolution loss, small light pipe volumes are employed. Typical GC-IR light pipes used with capillary gas chromatography columns have volumes of about 100 μL . To maximize IR radiation flux and optical path length, light pipes with diameters of about 1 mm and lengths of 12–15 cm are commonly employed. Light pipe ends must be sealed in order to conduct GC effluent without loss. This is accomplished by attaching IR transparent alkali halide windows to the light pipe ends. IR transparent gases such as He and N_2 are employed for the gas chromatographic mobile phase so that acquired spectra represent separated mixture components only. Vapour phase IR spectra obtained by light pipe GC-IR contain sharp spectral features because solute–solute interactions are minimal. When small molecules are detected at sufficiently high spectral resolution, vibration bands may exhibit rotational fine structure.

Subambient Solute Trapping GC-IR

Mixture components can be removed from GC effluent by trapping them on a cold surface. Subambient solute trapping GC-IR interfaces take advantage of the large differences between the volatilities of separated mixture components and GC carrier gas. When GC effluent is directed onto a surface maintained at a temperature at which mixture components condense but carrier gas does not, mixture components can be isolated from the GC carrier gas stream. In practice, mixture components are deposited on a cooled IR transparent window that is continuously moved during the chromatographic separation so that eluting solutes are deposited at different locations. IR analysis is achieved by measuring transmittance spectra of the frozen solutes. In contrast to light pipe GC-IR, trapped solute infrared measurements are not restricted to the time required for species to elute from the chromatographic column. Extended signal-averaging can be used to improve spectrum quality because IR analysis of frozen solutes is conducted off-line. Unlike light pipe GC-IR, subambient solute trapping GC-IR yields condensed phase IR spectra. Condensed phase spectra contain broader features than vapour phase spectra and reflect significant solute–solute interactions.

Matrix Isolation GC-IR

Matrix isolation GC-IR is a variation of the subambient solute trapping technique that yields significantly different spectral features. Rather than freezing mixture components, molecules are trapped within an inert argon matrix. Interactions between solute molecules are virtually eliminated by the argon matrix. As a result, spectra contain much sharper features than those obtained by

Figure 1 Gas chromatography-IR interfaces.

subambient solute trapping without matrix isolation. Instead of depositing solutes on a cooled infrared transparent window, matrix isolated species are formed on a reflective gold surface under vacuum and maintained near 10 K. Argon matrix gas is provided by using a pre-mixed GC carrier gas composed of helium and about 1% argon. Helium is not condensed at 10 K and is removed by the vacuum system. The argon and separated mixture components condense on the cryogenic surface. Because argon is present in the carrier gas at much higher concentration than mixture components, molecules deposited on the surface are surrounded by condensed argon. The argon matrix isolates individual solute molecules and prevents solute-solute interactions. IR spectra for separated mixture components are measured in a similar manner to that described for subambient solute trapping. However, reflectance rather than transmittance techniques are employed for IR analysis. Matrix isolation IR spectra exhibit sharp features because solute-solute interactions and molecular rotations are absent.

Liquid Chromatography-IR

Compared to GC-IR, liquid chromatography (LC)-IR measurements are often more challenging because mobile phases are not necessarily infrared transparent. Due to the fact that mobile phase concentration greatly exceeds that for mixture components in LC effluent, even mobile phases that have weak IR absorptivities can present significant problems. LC-IR interfaces can be categorized as flow cell or mobile phase elimination. **Figure 2** illustrates the three LC-IR interfaces described in the following sections.

Flow Cell LC-IR

LC-IR flow cells consist of two IR transparent windows separated by a spacer with a thickness that determines the cell path length. Alkali halide windows are commonly used with non-polar LC mobile phases, whereas zinc selenide windows are used with polar mobile phases. Unlike GC-IR, optimum flow cell path lengths for LC-IR are dictated by the absorptivity of the mobile phase. Path lengths of 0.1–0.2 mm are commonly employed with moderately absorbing mobile phases. For highly absorbing mobile phases (e.g. water), path lengths of about 10 μm are often required. Mixture component IR spectra are obtained from flow cell measurements after subtracting contributions from the mobile phase.

Aqueous solution IR analysis by flow cell LC-IR is particularly difficult because of the need for extremely short flow cell path lengths. Short path length flow cells are easily clogged and internal pressure fluctuations caused by mobile phase movement through the cell can appreciably change the IR beam path length. Fortunately,

Figure 2 Liquid chromatography-IR interfaces.

attenuated total reflection (ATR) provides an alternative method for attaining short path length IR spectrum measurements. ATR flow cells consist of a high refractive index infrared transparent material through which the IR beam is passed and around which LC mobile phase flows. When the incident IR beam angle at the ATR material/mobile phase boundary exceeds the critical angle, it is totally reflected. At each internal reflection, the electric field of the IR radiation penetrates slightly into the LC mobile phase. This 'evanescent wave' can be absorbed by species dissolved in the mobile phase. The penetration depth of IR radiation at each reflection varies with wavelength and is typically on the order of μm . By using appropriate length ATR materials, multiple reflections can be achieved to provide reproducible IR beam path lengths of 10–20 μm . Thus, by using ATR, short flow cell path lengths can be attained without the disadvantages of clogging and pressure fluctuations suffered by conventional flow cell designs.

Mobile Phase Elimination LC-IR

One method of avoiding the problems associated with the fact that most LC mobile phases absorb IR radiation is to remove these solvents prior to IR analysis. Like subambient solute trapping GC-IR, this approach exploits the differences between solute and mobile phase volatilities. By heating the end of the LC column, the mobile phase can be vaporized and removed by aspiration. Mixture components can then be deposited onto an IR transparent substrate. In early interface designs, solutes were deposited on IR transparent potassium chloride

powder contained in sample cups. In this system, multiple sample cups are contained in a rotating carousel. The carousel is rotated during LC separation to collect individual mixture components as they elute from the LC column. IR analysis is performed off-line by using diffuse reflectance optics. Like solute trapping GC-IR interfaces, there are no limits to the extent of signal averaging that can be applied to measure mobile phase elimination LC-IR mixture component spectra.

Column end heating can be an effective method for removing organic mobile phases such as *n*-hexane, but is not very effective for reverse phase separations that employ aqueous mobile phases. One method used to remove solutes from aqueous mobile phases is by extracting them into an organic solvent followed by solute deposition on an IR transparent substrate and solvent evaporation. However, on-line continuous solvent extraction greatly complicates LC-IR interfaces.

Microbore LC-IR

Although most LC separations are conducted with analytical scale columns, microbore LC columns provide better resolution and are becoming increasingly popular. The quantity of mobile phase needed for a separation by microbore LC is much less than that required for analytical scale LC separations. In addition, optimal flow rates for microbore LC are significantly lower than for analytical scale LC. These features of microbore LC simplify both flow cell and mobile phase elimination approaches to LC-IR. In addition, because small quantities of mobile phase are employed for microbore LC separations, expensive mobile phases that may not otherwise be practical can be employed. For example, the C-H stretching region of solute IR spectra can be accessed in reverse phase flow cell LC-IR measurements by employing deuterated solvents such as D₂O and CD₃CN as mobile phases. Because small amounts of mobile phase are employed for microbore LC-IR, less solvent must be removed to achieve mobile phase elimination. Rather than using a carousel of sample cups, a single IR transparent window (or reflective surface) that is moved beneath the column exit can be employed to collect mixture components.

Supercritical Fluid Chromatography-IR

Supercritical fluid chromatography (SFC) is often employed for separations involving non-volatile or thermally labile species that cannot be separated by GC or LC. Supercritical mobile phases (typically CO₂) have viscosities and solute diffusivities that are intermediate between those for gases and liquids. Supercritical CO₂ is created by subjecting the gas to high pressures. SFC-IR flow cells are made from high pressure UV flow cells by replacing the quartz windows in these cells with infrared

transparent windows. Alternatively, light pipe flow cells similar to those employed for GC-IR can be used for SFC-IR. In either case, regions in which CO₂ strongly absorbs are opaque in spectra measured by using flow cell SFC-IR. Mobile phase elimination SFC-IR techniques are particularly effective because supercritical CO₂ mobile phase readily vaporizes when exposed to ambient conditions. The same methods used for mobile phase elimination LC-IR are applicable to mobile phase elimination SFC-IR. Matrix isolation SFC-IR can be achieved by using the same apparatus employed for GC-IR but with CCl₄ instead of argon as the matrix substance. To prevent CO₂ condensation, the matrix isolation deposition surface temperature must be maintained at 150 K for matrix isolation SFC-IR.

Thin Layer Chromatography-IR

Two FT-IR sampling methods are commonly employed to measure IR spectra of mixture components separated by thin layer chromatography (TLC). Diffuse reflectance and photoacoustic IR spectroscopy are techniques that can be employed when sample materials are opaque.

Diffuse Reflectance TLC-IR

Diffuse reflectance (DR) IR analysis can be used to obtain IR spectra of species separated by TLC without removing them from the TLC plate. TLC plates containing spatially separated mixture components are passed through an optical system that focuses the incident IR beam onto a small spot on the plate and collects the resulting diffusely scattered IR radiation. **Figure 3** illustrates the basic principle. When the focused beam strikes a region of the TLC plate that contains solute, the resulting diffuse reflectance spectrum is characteristic of the solute and the TLC stationary and mobile phases. Solute spectra are obtained after subtracting the IR spectral features of the stationary and mobile phases. Little solute spectral information can be obtained in wavelength regions in which the stationary phase is highly absorbing. In addition,

Figure 3 Thin layer chromatography-IR interfaces.

interactions between solutes and the stationary phase often result in absorbance band wavelength and intensity differences relative to spectra measured for the same substance pressed into a KBr pellet.

Photoacoustic TLC-IR

In contrast to most other IR analysis techniques, the photoacoustic (PA) IR spectroscopic signal is a direct measure of the amount of radiation absorbed by the sample. Consequently, samples need not be transparent or reflective to be analysed by this method. However, TLC separated solutes must be physically removed from the TLC plate prior to analysis because PA-IR requires samples to be sealed in an air-tight chamber. As with diffuse reflectance measurements of TLC separated solutes, PA-IR spectra contain features representing stationary phase and residual mobile phase in addition to the solute. Spectral subtraction is employed to isolate solute spectra from PA-IR spectra. The main disadvantage of PA-IR compared to diffuse reflectance is that the locations of mixture components on the TLC plate must be known before infrared analysis can be performed. When solutes cannot be detected visually, an additional detector must be used to track solute migrations.

Solute Transfer TLC-IR

IR spectra of TLC-IR solutes obtained by DR-IR and PA-IR exhibit band intensity distortions in spectral regions in which stationary and mobile phases absorb and may not resemble those obtained for the same substances by KBr pellet transmittance measurements. To avoid stationary and mobile phase interferences, solute transfer methods can be used to physically move separated mixture components from the TLC plate to an infrared transparent substrate. Solute transfer is accomplished by subjecting the developed TLC plate to a second solvent that is applied orthogonally to the direction of the chromatographic mobile phase flow. This causes separated mixture components to move to the edge of the TLC plate where they are collected on IR transparent KCl powder. **Figure 3** illustrates the basic principle. Solute spectra subsequently obtained by diffuse reflectance IR analysis are similar to those obtained by KBr pellet transmittance measurements.

Chromatography-IR Interface Characteristics

Compared to mobile phase elimination techniques, flow cell chromatography-IR interfaces are simpler and less expensive. However, flow cell chromatography-IR yields optimal results only when the mobile phase is IR transparent. Detection limits in the low nanogram range can be

attained by light pipe GC-IR. Due to mobile phase absorbances, detection limits for flow cell LC-IR and SFC-IR combinations are higher than for light pipe GC-IR. In fact, flow cell LC-IR detection limits vary considerably and are primarily determined by the mobile phase absorptivity.

In general, mobile phase elimination chromatography-IR methods provide lower detection limits than flow cell approaches. The primary goal of mobile phase elimination is to remove interfering absorbances from acquired IR spectra. In addition to removing the chromatographic mobile phase, these interfaces concentrate solutes prior to IR analysis, which enhances solute infrared absorbances. Furthermore, off-line IR analysis by mobile phase elimination chromatography-IR facilitates increased signal averaging when compared to flow cell interfaces. When spectral noise sources are random, FT-IR spectrum signal-to-noise ratios are proportional to the square root of the number of scans averaged. The advantages of increased solute concentration and extended signal averaging are evidenced by the fact that typical solute trapping GC-IR detection limits are about ten times lower than those provided by light pipe GC-IR despite the fact that GC-IR mobile phases are infrared transparent.

Introduction

Chromatography is an important tool in purification and isolation of compounds from (complex) mixtures prior to mass spectrometric analysis. Mass spectrometry can be used to detect the compounds separated by chromatography. This can be performed off-line, that is after fraction collection, but an even more powerful and versatile technique is achieved when the separation is coupled on-line to mass spectrometric detection. The on-line combination of a chromatographic separation method and mass spectrometry (MS) is an important and versatile tool in many areas of analytical chemistry. In principle, it enables the mass spectrometric characterization of components in complex mixtures after separation, with minimal or no sample losses. Both major and minor components in a mixture are amenable to such a technique. Furthermore, MS offers advantages in quantitative analysis, that is enhanced selectivity by the use of high-resolution MS or tandem MS (MS/MS) and the use of stable isotopically labelled internal standards, which optimally mimic the properties of the analytes during sample pre-treatment, separation and detection.

Initially, in the mid-1960s the on-line combination of gas chromatography (GC) and MS was developed, first for packed columns and soon after their introduction, also for capillary columns. The introduction of quadrupole mass analysers greatly facilitated GC–MS because of their faster scanning and less stringent vacuum restrictions. They are now the most widely applied mass analysers for on-line chromatography-MS. The success of GC–MS initiated in the mid 1970s research into the on-line combination of liquid chromatography (LC) and MS. Subsequently, other separation techniques were successfully coupled to MS, for example supercritical fluid chromatography (SFC), thin-layer chromatography and various electromigration techniques like capillary zone electrophoresis (CZE) and electrochromatography. The actual breakthrough of LC–MS as a routinely applicable analytical technique took place in the mid 1990s.

General Instrumentation

The general instrumentation for on-line chromatography-MS consists of a conventional chromatograph, the

outlet of which is connected to an interface and a mass spectrometer (see **Figure 1a**). The main function of the interface is to protect the high-vacuum system of the mass analyser from too high gas loads from the chromatograph. Simultaneously, the interface should transfer as much of the analytes eluting from the column as possible to the mass analyser. While initially interfaces were developed to keep as much of the carrier gas or mobile phase out of the high vacuum, the development of LC–MS especially resulted in changes in this function of the interface. In the current LC–MS interfaces, the mobile phase plays an essential role in analyte transfer and ionization.

Gas Chromatography–Mass Spectrometry

The on-line capillary GC–MS combination can be achieved in two ways, that is via direct coupling or via an open-split coupling.

The gas flow through a typical 0.25-mm-ID capillary GC column matches the allowable gas load of a simple single-stage MS vacuum system. Since the components eluting from the GC column are already in the vapour state, immediate introduction of the capillary column effluent into the MS ion source in electron ionization

Figure 1 Schematic diagrams of chromatography-mass spectrometry systems: (a) GC–MS system, (b) atmospheric-pressure ionization LC–MS system.

mode is possible. Although frequently applied, this direct coupling has some disadvantages. The column outlet is at high vacuum, which results in changing retention times relative to other GC detectors, such as the flame ionization detector. Furthermore, the gas load to the ion source changes during the temperature programme of the GC analysis. This may influence the tuning of the ion source parameters. The problems related to the effect of the solvent load on the lifetime of the heated filament are easily overcome by switching off the filament during the first few minutes of the analysis.

An alternative to direct coupling is the open-split coupling; a schematic diagram of such a device is shown in **Figure 2**. The column is connected with the ion source via a fixed restriction. A make-up gas flow is provided either to raise the column flow to match the restrictor throughput or to rapidly remove the excess of carrier gas. As a result, the column outlet is at atmospheric pressure, just as in a conventional GC detector. By increasing the makeup flow it is possible to efficiently divert high vapour loads from the solvent away from the MS.

Liquid Chromatography–Mass Spectrometry

For a number of reasons, the on-line coupling of LC–MS appeared far more difficult to accomplish than the GC–MS coupling.

1. The gas load to the vacuum system resulting from evaporating the mobile phase in LC is generally much higher than in GC.
2. The mobile phase composition (containing non-volatile additives such as phosphate buffers) is often incompatible with MS.
3. The transfer of polar and ionic analytes from the liquid to the gas phase is difficult.

To solve the first problem a number of LC–MS interfaces have been developed, some of which are discussed in more detail in the subsequent paragraphs. The second problem must be solved at the chromatography stage, for example by changing to volatile buffers or the use of column switching. The third problem is largely solved by the advent of new liquid-based soft ionization techniques, especially thermospray and electrospray, which were

Figure 2 Open-split coupling for GC–MS.

actually developed in the course of LC–MS development.

A variety of interfaces was developed for on-line LC–MS coupling. A number of these found wide application when they became commercially available, for example the moving-belt interface, direct-liquid introduction, thermospray, particle-beam and continuous-flow fast-atom bombardment (Cf-FAB), but these are hardly used any longer due to the introduction of interfaces based on atmospheric pressure ionization (API), that is electrospray and atmospheric-pressure chemical ionization (APCI). Before discussing the API-based interfaces in detail, brief attention is given to three of the older LC–MS interfaces.

In a particle-beam interface (**Figure 3a**), the column effluent is pneumatically nebulized into an atmospheric-pressure desolvation chamber. This is connected to a momentum separator where the analytes are transferred to the MS ion source while the low molecular mass solvent molecules are efficiently pumped away. The analyte particles hit the heated source surface, evaporate

Figure 3 Older types of LC–MS interfaces: (a) particle-beam interface, (b) thermospray interface, and (c) target area of continuous-flow fast-atom bombardment interface.

and can be ionized by electron or chemical ionization. The evaporation step obviously limits the application range of the interface to not-too-polar analytes.

In a thermospray interface (**Figure 3b**), the column effluent is rapidly heated in a narrow bore capillary such that partial (ca. 90%) evaporation of the solvent is achieved inside the capillary. As a result, a mist of vapour and small droplets is formed in which the heated droplets further evaporate and ions are generated, either by the thermospray ionization process based on ion evaporation or by solvent-mediated chemical ionization initiated by electrons from a heated filament or a discharge electrode. The excess vapour is pumped away directly from the ion source.

In a Cf-FAB interface (**Figure 3c**), a small mobile-phase stream, containing glycerol as a FAB matrix, flows towards a FAB target where the effluent is bombarded by fast atoms or ions to achieve analyte ionization. Non-evaporated mobile phase constituents are collected in a wick, which is a compressed paper pad which has to be regularly renewed.

Interfaces Based on Atmospheric-Pressure Ionization

After initial attempts in the mid 1970s, LC-MS interfaces based on API were developed in the mid 1980s. An API mass spectrometer differs from a conventional instrument because ions are generated in an atmospheric-pressure region and subsequently introduced into the

high vacuum mass analyser. The difference is clearly depicted in **Figure 1b**: the ion source and the interface to vacuum are interchanged. In an API interface, the sample can be introduced in two different ways and ions can be produced in two different ways, that is by electrospray or by APCI. After ionization, the ions generated are transferred to the mass analyser via an API interface (**Figure 4**), which is independent of the mode of sample introduction or ionization. LC-MS interfaces based on API nowadays are by far the most widely used.

API interfacing thus comprises a number of steps:

1. Nebulization of the column effluent into small droplets followed by their rapid evaporation. Nebulization is achieved either by pneumatic nebulization in combination with a heated zone (APCI), or by (pneumatically assisted) electrospray nebulization due to the action of a high electric field on the liquid in a narrow-bore needle. Schematic diagrams of the spray probes are shown in **Figure 4**.
2. Generation of ions, either by gas-phase ion-molecule reaction initiated by electrons from a corona discharge needle, where the solvent acts as the reagent gas (APCI), or by ion evaporation of preformed ions in solution (electrospray ionization).
3. Sampling of ions from the atmospheric-pressure region into a two-stage differentially pumped interface, which enables sufficient pressure reduction and transfers the ions to the mass analyser in a high-vacuum chamber.

Figure 4 Atmospheric-pressure interface for LC-MS with electrospray and heated nebulizer APCI spray probes.

4. Mass analysis of the ions and subsequent detection.
5. Data acquisition and handling.

Electrospray Interfacing and Ionization

The electrospray spray probe typically consists of a 100 μm i.d. stainless steel or fused-silica capillary surrounded by a coaxial tube for the nebulization gas. The nitrogen nebulization gas allows the introduction of flow rates in excess of 10 $\mu\text{l min}^{-1}$ (pneumatically assisted electrospray or ionspray). The spray probe is positioned in the atmospheric-pressure ion source at a short distance from a counter electrode. A 2–3 kV electric field is applied between the needle and the counter electrode. This results in the formation of a fine aerosol of charged droplets from the spray probe. These droplets are rapidly evaporating, assisted by a concurrent, counter-current or perpendicular heated nitrogen gas stream, resulting in an increase in droplet charge at the surface. This leads to two competing processes: field-induced Rayleigh or electrohydrodynamic droplet disintegration, leading to an explosion of the initial droplet into a series of highly charged smaller offspring droplets, and field-induced ion evaporation, leading to desorption of preformed ions from the bulk solution into the gas phase. The ions generated are sampled by the mass analyser.

Although current electrospray interfaces can be used with flow rates of up to 1 ml min^{-1} , lower flow rates, for example 40–200 $\mu\text{l min}^{-1}$, are preferred in most LC–MS applications, thus requiring the use of either a postcolumn solvent splitter or microbore LC column.

Electrospray ionization is especially suited for the analysis of compounds that preform ions in solution, for example by acid–base chemistry, that is organic acids and bases, peptide and proteins, oligonucleotides, etc. For analytes with a molecular mass exceeding 500 Da and multiple protonation or deprotonation sites, multiply charged ions may be generated by electrospray ionization. This enables the mass analysis of biomacromolecules by means of a quadrupole mass analyser with a limited mass range. As such, electrospray plays an important role in the characterization of peptides and proteins by MS. Given the limited sample availability in many of these applications, nano-electrospray devices have been developed which allow the introduction of 0.01–1 $\mu\text{l min}^{-1}$ of protein solutions into the MS.

APCI Interfacing and Ionization

The APCI probe consists of a liquid introduction capillary surrounded by a coaxial tube for pneumatic nebulization. After pneumatic nebulization of the column effluent, the droplets are swept through a heated zone to achieve evaporation of the droplets. The solvent vapours

are subsequently used as reagent gas in chemical ionization, initiated by electrons from a corona discharge electrode kept at a few kV. In positive-ion mode, a series of gas-phase ion–molecule reactions leads to the formation of protonated solvent molecules which may react with the analyte molecules having a higher proton affinity than the solvent. The protonated analytes are sampled and subsequently mass analysed.

The APCI spray probe is readily applicable to a wide flow-rate range, for example between 0.2 and 2 ml min^{-1} . It allows the ionization of analytes in a wide polarity range. It can be used with both typical reversed-phase LC mobile phases (mixtures of water and methanol or acetonitrile) and pure organic solvents. APCI is a highly efficient ionization technique.

API Interfacing in More Detail

After the generation of ions in the atmospheric-pressure ion source by either electrospray or APCI, the ions are sampled into the multistage differentially pumped vacuum system. Different ion sampling devices are applied by different instrument manufacturers: a glass capillary with metallized ends, a heated stainless steel capillary, or a sampling orifice or cone. The low-pressure side of the ion sampling device acts as a nozzle in a molecular-beam source: expansion of the gas–vapour–ion mixture takes place. The core of the expanding jet, primarily containing the constituents with the higher mass, is sampled by a skimmer. To preferentially sample the ions in the jet, a ring electrode is positioned between the nozzle and the skimmer. The region between the nozzle and skimmer is kept at a pressure of ca. 100 Pa. After sampling by the skimmer, a second expansion stage takes place in the ion optics region, kept at a pressure of 0.1–1 Pa by means of a turbomolecular pump. The ion optics region contains a quadrupole, hexapole or octapole ion guide, which efficiently transports the ions towards the mass analyser, housed in the third pumping stage, kept at a pressure below 10^{-3} Pa by means of a second turbomolecular pump.

The transfer of ions from an atmospheric-pressure region through a series of differentially pumped vacuum chambers can be used to collisionally induce fragmentation of these ions in the transition region, for example by increasing the potential difference between the nozzle and the skimmer or between the skimmer and the multipole ion guide. This in-source CID approach is successfully applied in structure elucidation of unknown compounds. To obtain well-interpretable mass spectra after in-source CID, either pure compounds or well-separated compounds should be used, because (in contrast to CID in an MS/MS instrument) this CID is done without prior precursor-ion selection.

Mass Analysis API Interfacing

Although the mass analysis after API interfacing is in most cases performed using a (triple) quadrupole instrument, API devices have also been developed (and are commercially available) for other types of mass analysers, that is ion-trap, time-of-flight (TOF), magnetic sector and Fourier-transform ion-cyclotron resonance (FT-ICR) instruments as well as a number of hybrid instruments, such as quadrupole-TOF and magnetic sector-ion-trap instruments. In particular, the combination of API with ion-trap and TOF instruments has received considerable attention because of the favourable price to performance ratio of these instruments in a number of applications, compared to triple-quadrupole instruments. The extremely high resolution achievable with FT-ICR can especially be useful in determining charge states of multiply charged protein ions after fragmentation.

Data Acquisition and Handling

The mass spectrometer has two general modes of data acquisition:

1. The full-scan acquisition mode, where a series of complete mass spectra is acquired as a function of time.
2. The selected-ion monitoring (SIM) mode, where the intensity of selected ions with particular m/z is acquired as a function of time.

Choosing between these two modes is a matter of striking a compromise in the particular application between maximizing the measurement time of a particular m/z (in SIM mode), which is favourable for sensitivity, and the information content (in full-scan mode), which is favourable in identification and structure confirmation.

The data acquisition results in a three-dimensional data-array with ion intensity, m/z , and time or scan number as the three dimensions. This data-array can be handled in various ways. For the total-ion chromatogram, the ion intensities in each scan are summed irrespective of the m/z of the ions and the summed intensity, that is the total-ion current, is plotted as a function of time. In this mode the mass spectrometer acts as a universal detector. In GC-MS, the total-ion chromatogram largely resembles the chromatogram obtained via flame-ionization detection. In a base-peak chromatogram, the intensity of the base peak irrespective of the m/z , that is the most intense peak in each mass spectrum, is plotted as a function of time. This mode can be useful for peak finding in applications with high background levels, for example in LC-MS with API interfacing. In a mass chromatogram, the ion

intensity for an ion or a series of ions with particular m/z is plotted as a function of time. In this mode the mass spectrometer acts as a specific or selective detector. And finally, in the mass spectrum, for each scan number, the ion intensity can be plotted as a function of the m/z . Summed, averaged and background-corrected mass spectra over a series of scans can be made as well. The mass spectrum can be computer-searched against a mass spectral library.

Additional and Advanced Techniques

The performance of on-line chromatography-MS can for some applications be greatly enhanced by the use of additional techniques. On-line chromatography-MS should be considered as an integrated and hyphenated approach, where all system parts should be optimally tuned for the complete system. The combination of a potentially high-efficiency separation and a potentially high-selectivity detection enables a number of problem-oriented analytical strategies, for example directed at identification of minor impurities in complex samples, requiring highly efficient separation combined with MS in full-scan mode, offering the highest information content or directed at high-throughput target compound analysis, where the separation efficiency is deliberately reduced to save analysis time and the high selectivity afforded by either high-resolution MS or tandem MS is applied selectively to detect the compounds of interest within the matrix.

One further development has been the combined online coupling of both NMR spectroscopy and mass spectrometry to chromatographic separations. This is usually realized in the form of HPLC-NMR-MS where the NMR and MS detection is carried out in parallel, with the eluent from the column typically being split 95:5 for NMR and MS respectively.

Analyte Derivatization

Capillary GC-MS is an extremely powerful approach, combining the high separation efficiency of the capillary GC column with the identification power of the MS in electron-ionization mode. However the applicability range of GC is limited to relatively volatile compounds. To widen the applicability range, pre-column analyte derivatization strategies are often applied to enhance the volatility of the analytes. Methylation, silylation and acetylation reactions are most often applied for the analysis of compounds with amine, (poly-) hydroxy and carboxylic acid functional groups. Furthermore, derivatization to pentafluorobenzyl derivatives is applied to enhance the sensitivity of analytes in electron-capture negative-ion chemical ionization.

Tandem Mass Spectrometry

A powerful tool to enhance the analytical potential of combined chromatography-MS, especially in LC-MS, is tandem MS (MS/MS). MS/MS was first introduced as a way to induce fragmentation of ions generated in the ion source, for example by soft ionization methods, and after their mass selection. In such an experiment, the first mass spectrometer selects a particular precursor ion, which is (collisionally) dissociated, and the product ions are analysed with the second mass spectrometer. This is the product-ion scan mode which is primarily used to elucidate the structures of ions.

For the analytical use of MS/MS, other scan modes can be useful as well as the product-ion scan mode. The various modes are explained and summarized in **Table 1**. The precursor-ion and neutral-loss scan modes are particularly useful in screening. They are part of a powerful analytical strategy applicable in impurity, degradation product and metabolite profiling, as well as other applications where searching for structurally related compounds is important. After an appropriate ionization mode is found, a product-ion mass spectrum is obtained for the parent compound. In this spectrum, possible common precursor ions and common neutral losses have to be identified.

As an example, the screening for unknown metabolites of heptabarbital can be considered (see **Figure 5**). The fragmentation of heptabarbital under CID is also shown in **Figure 5**. Knowing that most of the metabolism of this drug primarily involves the cycloheptene ring, the barbituric acid related product ion at m/z 157 can be used as a common precursor ion to screen for compounds characterized by metabolism of the cycloheptene ring. Alternatively, the neutral loss of 156 Da can be applied in screening.

Table 1 Scan modes in MS/MS

Mode	MS1	MS2	Application
Product-ion	Selecting	Scanning	To obtain structural information by CID of ions produced in the source
Precursor-ion	Scanning	Selecting	To monitor compounds which in CID give an identical fragment
Neutral-loss	Scanning	Scanning	MS1 and MS2 are scanning at a fixed m/z difference; to monitor compounds that lose a common neutral species
Selective reaction monitoring (SRM)	Selecting	Selecting	To monitor a specific CID reaction

Subsequently, these precursor-ion and neutral-loss scans are performed, preferentially with on-line chromatographic separation. In this way, the m/z for related compounds can be found. Product-ion mass spectra are obtained based on these m/z . Interpretation of the mass spectra leads to identification of the related compounds, impurities or metabolites. Neutral-loss scans of 176 Da and 80 Da can be applied to screen for *O*-glucuronide and aryl-*O*-sulfate conjugates of drugs, respectively.

Selective reaction monitoring (SRM) is extremely useful in quantitative environmental and bioanalyses, where interfering sample matrix components may adversely influence the achievable detection limits. The enhanced confidence level in SRM, based on the monitoring of a specific chemical reaction in the gas phase, made LC-MS/MS in SRM mode the analytical method of choice in quantitative bioanalysis during drug development and clinical trials by pharmaceutical industries. In addition, the monitoring of a specific collision-induced reaction by SRM significantly improves the selectivity, resulting in greatly improved signal-to-noise ratios and enabling a limited sample pre-treatment prior to LC-MS/MS analysis, thereby increasing the sample throughput.

Coupled Column Chromatography

One of the major difficulties in LC-MS coupling is that the prolonged use of non-volatile mobile-phase additives such as phosphate buffers and sodium dodecyl sulfate, is prohibited. In most applications, the non-volatile additives can successfully be replaced by a volatile alternative, such as ammonium acetate and heptafluorobutyric acid. When this is not possible without significant influence on the chromatographic resolution, the use of column-switching approaches may be useful, especially in target-compound analysis. The chromatography is performed on a first column under optimized chromatographic conditions. Compounds of interest are trapped onto short

Figure 5 Product-ion mass spectrum of heptabarbital.

trapping columns, which are switched in-line during appropriate retention time windows. These loaded trapping columns are subsequently eluted with a mobile phase and flow rate readily amenable to the LC-MS interface, either directly to the LC-MS/MS system (phase-system switching) or to a second column (coupled-column chromatography). These strategies may also provide (significant) improvements in selectivity. In this respect, the use of immunoaffinity chromatography as a first step can be extremely useful.

Capillary Zone Electrophoresis-MS

LC-MS interfaces have successfully been applied for the coupling to MS of other liquid-based separation techniques, such as SFC, CZE and electrochromatography. The coupling of the highly efficient CZE to MS has achieved most attention because of the high promise of this combination in the analysis of ionic compounds, peptides and proteins. On-line identification of minor impurities made observable by the high separation efficiency achievable in CZE would be extremely useful. On-line CZE-MS is relatively easy to accomplish via an electrospray interface, either via the use of a coaxial sheath liquid to make up the $\mu\text{L min}^{-1}$ flow rate from the CZE to the $5\text{--}10\mu\text{L min}^{-1}$ required in conventional electrospray interfaces, or via the use of a nano-electrospray interface that can accommodate $\mu\text{L min}^{-1}$ flow rates. However, as a result of the small injection volumes, the concentration detection limits reported are generally in the low ppm range. Various on-line strategies have been proposed to improve these detection limits, for example on-line pre-concentration via isotachopheresis, solid-phase extraction or liquid-liquid electroextraction. In general, these strategies are target-compound directed and therefore appear not to be particularly useful in general impurity profiling.

Application Areas of Chromatography-MS

Both GC-MS and LC-MS are widely applied in many fields. As indicated, GC-MS is limited to relatively volatile compounds. Within this restriction, GC-MS is widely applied to the identification and quantitation of compounds of environmental and pharmaceutical interest. In areas such as the characterization of oil fractions, environmental monitoring, for example of chlorinated pesticides like DDT, and also of chlorinated dibenzodioxins, dibenzofurans and related compounds, and in a number of routine analytical procedures, for example in a number of clinical assays, in doping analysis in sports and for forensic purposes, GC-MS shows unsurpassed analytical possibilities, in terms of both sensitivity and identification power.

LC-MS finds wide application in the analysis of compounds that are not amenable to GC-MS, that is compounds that are highly polar, ionic and thermolabile, as well as (bio)macromolecules. In environmental applications, LC-MS is applied, often in combination with off-line or on-line solid-phase extraction, to identify pesticides, herbicides, surfactants and other environmental contaminants. LC-MS plays a role in the confirmation of the presence of antibiotic residues in meat, milk and other food products. Furthermore, there is a substantial role for LC-MS in the detection and identification of new compounds in extracts from natural products and the process control of fermentation broths for industrial production of such compounds, for example for medicinal use. LC-MS technology is also widely applied in the characterization of peptides and proteins, for example rapid molecular-mass determination, peptide mapping, peptide sequencing and the study of protein conformation and non-covalent interactions of drugs, peptides and other compounds with proteins and DNA. However, the most important application area of LC-MS is in the pharmaceutical drug development area, where LC-MS is involved in almost every stage of development, for example rapid characterization based on the molecular mass of medicinal combinatorial libraries, the detection and identification of drug metabolites, reaction by-products and drug degradation products. LC-MS/MS in SRM mode is currently the method of choice in high-throughput quantitative bioanalyses for bioavailability studies, pharmacokinetic and pharmacodynamic studies and during clinical trials.

Symbols

a	hyperfine interaction constant
A	absorption
E	emission
I^* and I_0	intensities of the polarized and equilibrium signal
J	spin–spin coupling constant
J_e	electron exchange interaction
m	absolute enhancement factor of product polarization
M	multiplet effect
N	net CIDNP effect
S	singlet state
t	time
T_0	triplet zero state
T_{1N}	nuclear spin–lattice relaxation time
T_{1R}	nuclear spin–lattice relaxation time in a radical
γ	parameter for location of the magnetic nuclei in the radicals
Δg	difference in the g -factors of the radical with polarized nucleus and the radical partner
ε	parameter for ‘in-cage’ or escape recombination
λ	parameter for recombination from S- or T-state
μ	multiplicity

The phenomenon of chemically induced dynamic nuclear polarization (CIDNP) consists of the manifestation of unusual line intensities and phases of signals of radical reaction products in the NMR spectrum when reaction takes place directly in the probe of the spectrometer. These anomalous lines (enhanced absorption or emission of NMR signals), which reflect the populations of nuclear spin states deviating from the Boltzmann condition, are observed within the time range of nuclear relaxation times of the diamagnetic molecules (T_{1N}), which are as a rule, several seconds to tens of seconds. Subsequently, the NMR spectrum re-acquires its usual form. In 1967, two research groups in Europe (J. Bargon, H. Fischer and U. Johnson) and the USA (H. Ward and R. Lawler)

discovered independently that this phenomenon is directly associated with the free radicals involved in the process. Later on, it was shown that this also pertains to radical ions and triplet excited states of molecules.

According to currently existing theory, the nonequilibrium intensities in NMR spectra are generated as a result of electron–nuclear interactions in the so-called radical pair. These are the pairs of paramagnetic particles that may originate during the homolysis of a molecule under the action of heating, light or ionizing radiation, as well as resulting from single-electron transfer between the donor and acceptor molecules and radical encounters in the bulk preceding the recombination.

It follows from the above discussion that, in principle, the CIDNP phenomenon can be observed for virtually all types of radical reactions. To date, various CIDNP techniques have been employed to clarify the role of radical species in redox reactions of organic compounds, nucleophilic and electrophilic substitution, addition and elimination reactions, isomerization processes, thermolysis and photolysis of organic peroxides and azo- and diazocompounds, a number of photosensitized processes, including the reactions of organoelement compounds of silicon, germanium, tin, mercury, aluminium, lithium, sodium, potassium, magnesium and organoxenon compounds, polymerization processes and a number of rearrangement reactions.

Note that prior to CIDNP studies, in certain cases, the involvement of paramagnetic species in the reactions had not even been anticipated. A good example is the process of sensitized *cis-trans* photoisomerization of substituted olefins. Moreover, CIDNP has brought unambiguous evidence of earlier-suggested single-electron transfer as the first stage of aliphatic nucleophilic substitution in the reaction of alkyl- and benzylhalides with alkyl derivatives of lithium.

The analysis of CIDNP effects allows information to be obtained on the structure and reactivity of active short-lived (from nanoseconds to microseconds) paramagnetic species (free radicals and radical ions, triplet excited molecules), and on molecular dynamics in the radical pair. The analysis makes it possible to distinguish between the bulk and ‘in-cage’ stages of complex chemical reactions. CIDNP data also provide information on the multiplicities of reacting states, which is of utmost importance for understanding photochemical processes.

CIDNP is not a direct method of detection of the structure of radical species: the information of hyperfine interaction (*hfi*) constants, *g*-factors and life-times of paramagnetic intermediates is obtained on the basis of the analysis of the phases and intensities of polarized lines in NMR spectra, as well as from CIDNP kinetics, and the dependence of polarization efficiency on the magnetic field strength applied to the sample during reaction. However, the simplicity and reliability of the identification of polarized lines in the NMR spectra ensure high plausibility of CIDNP-based structural and kinetic information.

Thus, nowadays CIDNP is one of the powerful techniques for the investigation of elementary stages of complex radical chemical reactions.

Nuclei Demonstrating the CIDNP Phenomenon

Chemical polarization is observed only for nuclei possessing a magnetic moment (spin). **Table 1** lists the principal nuclei for which CIDNP effects have been detected. At present, the majority of CIDNP experiments have been carried out for hydrogen (^1H) and fluorine (^{19}F) nuclei. Next in incidence are ^{13}C and ^{31}P . Unless otherwise specified, all further consideration will employ the parameters characteristic for ^1H CIDNP.

CIDNP Observation Techniques

The chemical reactions are most commonly run directly in the probe of an NMR spectrometer. Such chemical polarization formed in the magnetic fields of NMR spectrometers (with a strength of several tesla) is usually called CIDNP in high magnetic fields.

There exist other techniques of CIDNP observation as well. In these techniques, the reaction under study is carried out in a separate magnet, as a rule, with variable field strength, and afterwards the reaction mixture is transferred rapidly (with the characteristic time lower than $T_{1\text{N}}$) to the probe of the NMR spectrometer. The transfer is often performed by a flow system; however, other possibilities also exist.

Table 1 Nuclei which have been used in CIDNP studies

Nucleus	Spin
^1H	1/2
^2H	1
^{13}C	1/2
^{15}N	1/2
^{19}F	1/2
^{31}P	1/2
^{119}Sn	1/2

It is necessary to note that CIDNPs formed in high and low magnetic fields, such as the geomagnetic field, are two essentially different physical phenomena.

Types of CIDNP Effects

According to their manifestation, CIDNP effects can be subdivided into two types: net effects, that is enhanced absorption and emission of NMR signals, and multiplet effects, consisting of the redistribution of the line intensities between specific components of multiplet signals in the NMR spectrum (**Figure 1**).

CIDNP Effects in High Magnetic Fields

For the chemical application of CIDNP, it is important to be aware of the fact that in high magnetic fields the non-equilibrium population of nuclear spin sublevels is formed as a result of transitions solely between singlet (S) and triplet zero (T_0) states or a radical pair (**Figure 2**). These transitions occur due to interaction of an electron spin with spins of magnetic nuclei in the radical pair, and they are also dependent on the difference in *g*-factors of radicals in the radical pair.

Theory shows that in this case the probabilities of the formation of the singlet (recombining) state of a radical pair are different for α and β projections of nuclear spins. As a result, spins with a certain orientation predominantly appear in the 'in-cage' recombination product, while spins with an opposite orientation occur in products resulting from the escape of radicals into the bulk (**Figure 3**). According to the existing Kaptein rules modified by Closs, the sign of the net CIDNP effect (*N*) in high magnetic fields is defined by the following set of parameters:

$$N = \mu \cdot \varepsilon \cdot \Delta g \cdot \text{hfi} \cdot \lambda$$

where μ is the multiplicity of the precursor of the radical pair ('+' for triplet and '-' for singlet precursor), ε is '+' for 'in-cage' and '-' for escape recombination products, Δg is the sign of the difference in the *g*-factors of the radical with polarized nucleus and radical partner in the radical pair, *hfi* is the sign of the hyper-fine constant of a given nucleus in the radical under study, and λ is '+' for the radical pair recombining from an S-state and '-' for the radical pair recombining from a T-state (usually employed for radical ion reactions). The sign of *N* reflects the phase of the NMR signal of a given nucleus: '+' for enhanced absorption (*A*) and '-' for the emission (*E*).

There are also qualitative rules employed for the analysis of multiplet effects:

$$M = \mu \cdot \varepsilon \cdot \text{hfi}_1 \cdot \text{hfi}_2 \cdot J \cdot \gamma,$$

Figure 1 (a) Schematic presentation of the types of CIDNP effects: (1) equilibrium NMR spectrum, (2) enhanced absorption (A), (3) emission (E_2), (4) multiplet effect (A/E), (5) multiplet effect (E/A). (b) Experimental example of time-resolved (100 μ s after laser pulse) 250 MHz ^1H CIDNP spectrum, detected during the photolysis of substituted 1,2-dihydropyridine in the presence of 2,5-dichlorobenzoquinone: line assignment is shown on the structures; signal (6) is attributed to HDO admixtures in CD_3CN . The equilibrium signals were removed using the presaturation pulse sequence preceding the laser pulse.

Figure 2 Schematic presentation of the radical pair energy levels in (a) low ($H_0 \approx$ hyperfine interaction constant) and (b) high ($H_0 \gg$ hyperfine interaction constant) magnetic fields.

Figure 3 Distribution of chemical polarization between geminate (in-cage) and homogeneous products of radical reaction.

where μ and ε are defined as in the previous case, hf_1 and hf_2 are the signs of hyperfine constants of nuclei 1 and 2 in the radical forms, J is the sign of the spin-spin coupling constant of these nuclei in the molecule, γ is '+' if these nuclei belong to the same radical, and '-' if they belong to different radicals in the radical pair. The sign of M reflects two types of multiplet effect: '+' for E/A and '-' for A/E type effects.

Analysis of the detected net and multiplet effects is also performed by means of a comparison of the experimentally observed effects with those that are calculated.

For example, the above-mentioned qualitative rules are applicable for the analysis of CIDNP effects for all nuclei from **Table 1**, except for ^{119}Sn , which has a number of peculiarities stipulated by its anomalous magnetic resonance parameters (hyper-fine constant more than 0.16 T, g -factor 2.0160). To analyse CIDNP effects of this nucleus one has to employ a special theoretical approach.

Thus, analysis of the experimental sign of the CIDNP effects basically allows the above enumerated parameters of the radical pair to be singled out provided that all the others are known in advance. For example, the chemical shift of the polarized signal in an NMR spectrum and its multiplet structure often reveal the structure of the radical precursor of the polarized compound. In this case, this assumption is easily verified by substituting the magnetic resonance parameters of the suggested radical in the expressions mentioned earlier for the rules. Another possibility is the definition of the multiplicity of the reacting state for known compositions of the radical pair.

The enhancement coefficient serves as a basic quantitative feature of CIDNP. One usually distinguishes between the observed enhancement coefficient and the absolute one. The observed enhancement coefficient is defined as the ratio of the intensities of the polarized NMR signal to the equilibrium one recorded after the completion of the reaction. The time dependence of observed polarization on time (dI^*/dt) has two components, $(dI^*/dt)_{\text{react}}$ and $(dI^*/dt)_{\text{relax}}$, reflecting the contributions from chemical reaction and relaxation of CIDNP. As a first approximation, the relaxation of CIDNP occurs through spin-lattice relaxation, which suggests the following expression for the observed polarization:

$$\frac{dI^*}{dt} = \left(\frac{dI^*}{dt} \right)_{\text{react}} - \frac{I^*(t) - I_0(t)}{T_{1N}}$$

where I^* and I_0 are the intensities of polarized and equilibrium signal, respectively; $(dI^*/dt)_{\text{react}} = dI_0/dt \cdot m$, where m is the absolute enhancement factor of the product polarization. This expression implies that the observed polarization depends on the magnetic resonance parameters of the radical pair (hyperfine coupling, g -factors)

through m , radical relaxation times in the diamagnetic state, and the kinetics of the build-up of polarized products.

The absolute enhancement coefficient of CIDNP differs from the observed one in that the former is dependent only on the radical pair parameters. At present, the absolute enhancement coefficient can be reliably measured only for the case of photochemical reactions with the employment of specially elaborated time-resolved CIDNP techniques.

From the viewpoint of experimental techniques, the major potentialities are now realized for research into CIDNP in photochemical reactions. In this case, time-resolved techniques (so-called flash-CIDNP) are widely used. These techniques utilize laser-pulse photoexcitation with pulse detection of CIDNP effects. The solution of the sensitivity versus time-resolution dilemma stipulates the following restrictions of the attainable time resolution: the duration of the detecting radiofrequency pulse should not be shorter than 100 ns, otherwise the sensitivity of the NMR method is lost. Shorter pulses can be employed only to study the processes demonstrating an extreme absolute enhancement coefficient of CIDNP. The latter are characteristic only for a limited number of model reactions, for example the photolysis of cyclic ketones.

The improvement of time resolution is possible when using both a standard NMR spectrometer and modified equipment. These techniques differ by the methods of mathematical processing of the experimental data when estimating the kinetic parameters.

Even in the simplest case of a microsecond time range, the time-resolved techniques allow one to observe homogeneous and geminate processes separately. The homogeneous processes include bimolecular recombination in the bulk, degenerate electron exchange reactions, proton exchange and various rearrangement reactions which also occur in the bulk.

CIDNP Effects in Low Magnetic Fields

A low magnetic field is defined as one in which the energy of the Zeeman interaction is of the same order of magnitude as the hyperfine interaction (see **Figure 2**). Therefore, a non-equilibrium population of nuclear states may arise not only via $S-T_0$ transitions, but also through $S-T_-$ and $S-T_+$ transitions between energy levels of a radical pair. The observed sign of CIDNP will predominantly depend on the difference in efficiencies of $S-T_{+,-}$ transitions.

As **Figure 2** suggests, the efficiency of $S-T_-$ and $S-T_+$ transitions also depends essentially on the magnitude and sign of the electron exchange interaction (J_e) in the radical pair. However, experimental studies on CIDNP in low magnetic fields show that for a radical pair comprising neutral radicals in non-viscous solutions, J_e does

not contribute significantly to the resulting polarization. The exceptions are radical ion pairs and biradicals.

To unravel the mechanisms of the elementary stages of radical reactions by means of the CIDNP method in low magnetic fields, one usually analyses the dependencies of CIDNP efficiencies on the magnetic field strength (field dependence of CIDNP). In this case, the data on radical pair composition are obtained on the basis of comparison of experimentally measured and theoretically calculated CIDNP field dependencies.

Comparison of CIDNP Techniques in High and Low Magnetic Fields for Investigation of Elementary Mechanisms of Radical Reactions

The basic distinction in the potential of application of these two techniques of CIDNP observation is stipulated by the difference in the mechanisms of their formation. Thus, formation of CIDNP effects in high magnetic field is not accompanied by flips of either electron or nuclear spin (for S and T_0 states the projection onto the magnetic field direction is equal to zero). Here, the radical reaction actually plays the role of dispatcher, directing radicals with α and β projection of nuclear spin to different products (see **Figure 3**). Thus, the formation of at least two products is a key element for CIDNP manifestation. This condition essentially narrows the range of processes open for investigation. Thus, so-called crypto-radical reactions, which are rather widespread in chemical practice, fall outside of the consideration range. To study these processes it is recommended CIDNP in a low magnetic field is used.

In the case of CIDNP in low magnetic field, the true non-equilibrium population of nuclear sublevels results from simultaneous flips of both electron and nuclear spins (see **Figure 2**). Therefore, in this case, the formation of the single product does not preclude the observation of CIDNP. A number of other reasons also stipulate the greater versatility of chemical polarization in low magnetic fields, namely, the greater observed enhancement coefficients as compared to those in a high magnetic field and the potential to detect net polarization formed in the radical pair with identical radicals.

Examples of CIDNP Applications to the Structure Determination and Properties of Paramagnetic Species (Free Radicals, Radical Ions, Biradicals, Carbenes, Macromolecules)

CIDNP in Structural Chemistry

By now the analysis of CIDNP effects has produced a large set of useful structural data on the signs of

hyperfine constants, g -factor values of the radicals and the energies of electron exchange interaction in the radical pairs.

Of special value is the information on the so-called magnetic resonance parameters (hyperfine interactions and g -factors) that cannot be estimated easily by other magnetic resonance techniques in the case of short-lived radicals. The data obtained allow inferences to be made on the electronic structure of paramagnetic species (σ - or π -radical) and hence about their reactivity.

Among the main sources of such data are photolysis and thermolyses reactions of various organic peroxides, demonstrating ^1H , ^{19}F and ^{13}C CIDNP effects. As a rule, the mechanisms of these processes have been determined previously, and the multiplicity of the reacting state is also known. Thus, employing the rules for the analysis of multiple and net CIDNP effects in high magnetic fields (see the preceding text), one can sequentially determine either the signs of the hyperfine constants for the radical pairs or the sign of Δg .

To define the values of the hyperfine constants and the g -factors of the radical pairs the entire polarized spectrum is stimulated and compared with the experimental one. This approach has been employed to obtain the values of the hyperfine constants and g -factors listed in **Table 2**.

For example, it follows from **Table 2** that the bonds in the cyclopropyl free radical are flexed, and the proton in position 1 protrudes out of the plane of the three-membered ring, since the hyperfine constant of this proton is much lower than that observed in a methyl radical (2.3 mT).

Aside from hyperfine constants and g -factors, the analysis of the multiplet effect in the photolysis products of cyclopropyl peroxide and, cyclopropene has defined the sign of the vicinal proton–proton spin–spin coupling constant ($J_{\text{H-H}} > 0$) which was unknown earlier.

The analysis of CIDNP effects has also made possible the determination of the structures of a number of radical ions of cyclic compounds (benzonorbornadiene, trialkylcyclopropanes, *syn*- and *anti*-paracyclophanes, etc.).

For example, the structure of the radical cation of 1,2-diphenylcyclopropane has been assigned on the basis of the analysis of ^1H CIDNP data formed in the act of photoinduced reversible electron transfer from cyclopropane to chloranil. The choice has been made between ‘closed’ and ‘open’ structures of the radical cation of 1,2-diphenylcyclopropane (**Figure 4**). The observed CIDNP effects of 1,2-diphenylcyclopropane (absorption of aromatic *ortho*-, *para*-, and H_α , and the emission of H_β) comply only with the ‘open’ structure.

CIDNP is also a method of determining nuclear spin–lattice relaxation times of free radicals and radical ions ($T_{1\text{R}}$). This approach was used to determine the $T_{1\text{R}}$ values of the CH_2 protons of benzyl (3.5×10^{-4} s),

Table 2 Magnetic properties of free radicals defined by means of CIDNP

Radical	Hyperfine interaction constant	Spin density, ρ_π	<i>g</i> -factor
	^{19}F : $a_4 > 0$ ^{13}C : $a_2 > 0$	$\rho_1 > 0$ $\rho_2 < 0$ $\rho_3 < 0$ $\rho_4 > 0$	
	^{19}F : $a_2 > 0$ $a_3 > 0$ $a_4 < 0$		
	^1H : $a < 0$ (−2.3 mT)		2.0058

CIDNP Effects in Reactions Involving Carbenes and Biradicals

Paramagnetic species possessing two unpaired electrons (biradicals, carbenes and their analogues) have been intensively studied using CIDNP techniques in high and low magnetic fields. The involvement of biradicals in organic and biochemical reactions is postulated in a number of cases, but the physical methods (EPR, laser spectroscopy) have allowed the detection of their formation predominantly in the photolysis of cyclic ketones. These species have also served as models for detailed studies of CIDNP peculiarities for biradicals, as well as the distinction of these effects from the case of free radicals.

A major peculiarity is the contribution of $S \rightarrow T_{+,-}$ transitions to CIDNP, which is due to the electron exchange interaction between the spins of unpaired

electrons (see the section ‘CIDNP effects in low magnetic fields’).

If the processes taking place in a biradical allow the possibility of the selection from nuclear spin states, the $S \rightarrow T_0$ transitions can also manifest themselves.

Reference data on biradicals of cyclic ketones point to the appearance of CIDNP effects in a wide range of magnetic field strengths. The manifestations of various mechanisms of CIDNP formation depend on the structure of the biradical.

As a rule, the field dependence of CIDNP shows up as curves with extrema, which are located in the magnetic field with the strength of about J_e .

Comparatively low values of J_e (< 0.1 T) are characteristic of flexible biradicals with a long carbon chain (C_8 and more) separating the radical centres. Therefore, one might expect the manifestation of an $S \rightarrow T_-$ mechanism (for $J_e > 0$, $S \rightarrow T_+$ mechanism) in low magnetic

fields, while in a high magnetic field the $S-T_0$ mechanism will manifest itself.

Large J_e values are typical of short biradicals (C_7 and shorter). In this case the extremum will appear in a magnetic field similar to that of conventional NMR spectrometers, $J_e > 1$ T. Therefore, in this case only the $S-T_{+,-}$ mechanism of CIDNP formation will appear.

There are also so-called rigid biradicals whose structure does not possess a flexible carbon chain. In this case, J_e may be either very large or negligibly small, the latter case reflecting the orthogonality of the orbitals of unpaired electrons. In both cases, it is reasonable to expect the manifestation of the $S-T_0$ mechanism of CIDNP formation.

In the former case, the $S-T_0$ mixing results from the existence of well-known non-radiative transitions. Here, the energy of J_e is counterbalanced by a pool of vibrational degrees of freedom.

The manifestation of an $S-T_0$ mechanism of CIDNP formation in high magnetic fields has been observed recently for biradicals containing Group 14 elements (Si, Ge).

At present, the investigation of CIDNP field dependencies for products of transformation of biradicals is the most reliable indirect method of demonstrating the involvement of biradicals in chemical reactions. The structure of the biradical can be inferred by comparison of observed with calculated field dependences. For this purpose, one might employ various approximations of the radical pair described in a number of specialized monographs.

Reference data show the examples of CIDNP manifestations of triplet (ground) and singlet (excited) states of carbenes. The triplet state is observed in the reactions of diphenylcarbene and methylene, while the singlet state has also been detected in the case of methylene. The analysis of CIDNP effects has led to the following conclusions. In contrast to the generally accepted viewpoint expressed in the chemical literature, not only the triplet but also the singlet state of carbenes reacts via hydrogen or halogen atom abstraction from the partner rather than insertion into the corresponding bond.

1H CIDNP effects have also been observed in the reactions of carbenes containing silicon and germanium with various scavengers. In this case, the radical stages

have been detected in the reaction of singlet (ground) and triplet (excited) states of dimethylsilylene and -germylene.

CIDNP as a Method of Investigation of Spin and Molecular Dynamics in Radical Pairs

Research into spin dynamics is presented in numerous papers devoted to the definition of the range of values of J_e in biradicals. This approach also allows an estimate to be made of the range of J_e values in radical ion pairs.

A prominent example of the potential of the method for investigating molecular dynamics is the recent research into the process of protein folding by means of photo-CIDNP observed in stopped flow experiments. It has been shown that the use of the CIDNP technique in stopped flow experiments has certain advantages over the conventional NMR studies using flow systems. The sensitivity gain due to the CIDNP enhancement coefficient allows the folding processes to be studied on a time range two orders of magnitude shorter than those observable by means of conventional NMR methods. In the process under study, CIDNP results from photo-induced electron transfer between a flavin additive and tyrosine and other amino acids of the protein (hen egg lysozyme). After the refolding, the CIDNP disappears, since after the conformational changes in protein structure amino acids become inaccessible to the flavin species.

At present, CIDNP is virtually a unique technique for the detection of so-called weak interactions (with the energy lower than several kT) between the reagents in chemical reactions. This includes charge transfer complexes, exciplexes and donor-acceptor complexes. As a rule, the involvement of these complexes is confirmed by the data on multiplicity of the reacting state obtained on the basis of CIDNP analysis (see corresponding sections in this article on the analysis of CIDNP effects). For example, the inconsistency between the multiplicity estimated on the basis of CIDNP data and that expected for the known set of photochemical parameters has justified the suggestion of a triplet exciplex in the photo-oxidation of Hantzsch ester by quinones.

The alteration of the multiplicity in the reaction of silylene with CCl_4 observed in the 7,7-dimethyl-7-silanorbornadiene derivative in the presence of triphenylphosphine has served as proof of the complexation between dimethylsilylene and Ph_3P .

CIDNP in Reactions Involving Biologically Relevant Molecules

The CIDNP technique has made a decisive contribution to the widely discussed question of the role of single-electron transfer stages in biochemical processes. These are primarily the oxidation of organic substrates which

occur under the action of UV irradiation and electron acceptors, as well as the enzymatic processes involving oxygenases.

The CIDNP technique has been used to unravel the elementary mechanisms of the oxidation of NADH co-enzymes and their synthetic analogues, and substituted 1,4-dihydropyridines, in the presence of electron acceptors. The underlying mechanism of NADH transformation is the transition from the dihydropyridine ring to pyridine.

In this case, the basic question is whether this process occurs via the single act of hydride transfer, or the redox reaction includes the sequence of several elementary stages involving paramagnetic species.

Application of ^1H and ^{15}N CIDNP techniques has allowed the demonstration that the process under study indeed includes the sequence of radical stages. For unsubstituted dihydropyridines, this is a chain of $\text{e}^-\text{H}^+-\text{H}^\bullet$ transformations, while for substituted species and NADH, the sequence $\text{e}^-\text{H}^\bullet$ has been observed.

The CIDNP technique has also been used to reveal the role of radical species in the processes of photo-transformations of coenzyme B_{12} model compounds and *all-trans*-retinal.

ROA	Raman optical activity
UV	ultraviolet
VCD	vibrational circular dichroism

Historical Perspective

Circular dichroism (CD) is the differential absorption of left and right circularly polarized light (CPL) by a chiral substance. The phenomenon can occur for all wavelengths of light and results in 'vibrational' CD (VCD) in the infrared region and 'electronic' CD (ECD) in the ultraviolet (UV) and visible regions, corresponding to the different excitations induced in a molecule by the light; 'Raman Optical Activity' (ROA) is the analogous phenomenon for Raman scattering. The VCD and ROA techniques are described elsewhere in this encyclopedia; the section here concentrates on the instrumentation for ECD.

Of these different forms of chiroptical spectroscopy, ECD is by far the most commonly employed technique for investigating chiral substances and is, therefore, often referred to simply as 'CD.' Not least this choice is aided by the relatively small sample requirements (typically less than 1 mg) and wide variety of solution conditions that can be accommodated by ECD.

As early as 1811, Arago had discovered that quartz plates cause plane-polarized light to be rotated by different degrees with varying wavelength of light. This wavelength dependence of optical rotation, the basis of optical rotatory dispersion (ORD), was further elucidated by Biot and Fresnel in the following two decades. However, ORD subsequently received little experimental attention, with the primary experimental work being constrained to optical rotations of a single wavelength, the sodium D-line (589.3 nm). Apart from work by Tschugaefi and Rupe (early 1900s), the phenomenon of ORD remained a theoretical concern until the studies of Kuhn, Lowry, Mitchell, Levene, and Rothen in the 1930s.

Nonetheless, the technical difficulties of measuring ORD, primarily through photographic means, hampered the science until the development of photoelectric spectropolarimeters in the mid-1950s. Brand and Rudolph introduced the first photoelectric spectropolarimeter c.1956. During the subsequent 10 years various manufacturers, including Roussel-Uclaf, Jasco (1961 onwards, the ORD-UV-5 instrument being notable), and Bellingham and Stanley (otherwise known as Bendix-Ericsson or Bendix-Gillham-King), introduced new designs and automated spectropolarimeters with extended wavelength ranges, often taking advantage of a Faraday cell to electrically generate a compensating optical rotation.

The phenomenon of CD was discovered relatively soon after Arago's initial observations of ORD, with Hidingier reporting differential absorption of CPL by amethyst crystals in 1847. CD of copper and chromium tartrate solutions was later observed by Cotton in 1895–96. Its application to organic molecules awaited the pioneering work of Mitchell, Lowry, and Kuhn in the late 1920s and 1930s. The development of CD instrumentation broadly followed that for ORD and in the late 1950s the Roussel-Juoan dichograph was produced, based around the Pockel cell, a tetragonal crystal of monoammonium phosphate subjected to an electric field to generate circularly polarized light from linearly polarized light (LPL), a forefather of the photoelastic modulators (PEMs) used today. Jasco subsequently made an attachment for its ORD-UV-5 spectropolarimeter in order that it may measure CD; to this day, Jasco CD instruments are described by the company as 'spectropolarimeters' despite their now being designed to primarily measure CD not ORD.

Linearly, Elliptically, and Circularly Polarized Light

The properties of polarized light are of crucial importance to the operation of CD instruments and thus the main features are briefly recapped here.

LPL of a given wavelength λ and frequency ν is defined as having its electric field vector transverse to the direction of propagation, lying in a single plane and varying sinusoidally with time and space as depicted in **Figure 1(a)**. The equation for the electric field vector at a particular position z along the direction of propagation at time t can be written as follows:

$$A(z, t) = A_0 \sin\left(\frac{\omega z}{c_m} - \omega t\right) i$$

Figure 1 (a) (Top) linearly polarized light of wavelength λ , polarized in the vertical plane, showing the electric field vectors perpendicular to the direction of propagation through space; (b) (bottom) the light decomposed into two in-phase components with mutually orthogonal plane polarizations at $\pm 45^\circ$ to the original polarization. From Chiralabs Ltd., with permission.

where i is the unit vector in the direction of polarization, ω is the angular frequency ($2\pi\nu$), and c_m is the velocity of light in the medium, with the scalar amplitude being A_0 .

This LPL can be considered as composed of either two mutually orthogonal linearly polarized components, as in **Figure 1(b)**, or two oppositely handed circularly polarized components, as in **Figure 5(b)**. Both descriptions are equally valid and by modifying these components in various ways, a range of possible polarization states of light can be obtained.

Linearly Polarized Components

First (LPL), can be considered as being composed of two mutually orthogonal, in-phase, equal magnitude linearly polarized components with planes of polarization lying at -45° and $+45^\circ$ to the original plane, as in **Figure 1(b)**. In this figure, the directions of the component polarizations are denoted as u and v .

If the v component were to be retarded relative to the u component by a distance $\delta = \lambda/2$ and the components recombined, as depicted in **Figure 2**, then LPL would be regained, but the plane of polarization would be rotated through 90° . A similar result is obtained if the u component is retarded instead. This is the basis of a

'half-wave plate' for rotating plane-polarized light and applies for all retardations that are odd integer multiples of $\lambda/2$, the even integer multiples simply retaining the linear polarization at its initial state.

Alternatively, if the v component were to be retarded relative to the u component by a distance of $\delta = \lambda/4$ and the components recombined, then left CPL would be generated, as depicted in **Figure 3**. (By convention, a viewer looking at the oncoming light, back along the direction of propagation toward the source, sees the electric field describe an anticlockwise motion with time for left CPL and, correspondingly, a clockwise motion for right CPL; thus, at any point in time, left CPL spatially describes a left-handed helix and right CPL spatially describes a right helix.) An analogous result but generating right CPL occurs if the u component is retarded instead (which can alternatively be described as a negative retardation), as depicted in **Figure 4**. This is the basis of a 'quarter-wave plate' for converting plane-polarized light to circular polarization.

For retardations that are not integer multiples of $\lambda/4$ or $\lambda/2$, the situation is rather more complex and generally ellipsoidally-polarized light results. The degree of ellipticity can be described by the ratio of its minor to major axes, P_{minor} and P_{major} , respectively (as electric

Figure 2 Retardation of one component by $\lambda/2$ gives plane-polarized light with its plane of polarization rotated through 90° . From Chiralabs Ltd., with permission.

field vector amplitudes), to give an angular ellipticity of θ :

$$\tan \theta = \frac{P_{\text{minor}}}{P_{\text{major}}}$$

Now suppose, instead of retardation, the v polarized component underwent a reduction in magnitude (such as when it is absorbed). In this case, on combining back with its u polarized complement, plane-polarized light is regained albeit with a loss in amplitude, but with the plane rotated clockwise (following the viewing convention

Figure 4 Retardation of u component by $\lambda/4$ relative to v component gives right circularly polarized light. From Chiralabs Ltd., with permission.

described earlier). Correspondingly, a reduction in magnitude of the u polarized component gives rise to an anticlockwise rotation. This forms the basis of linear dichroism spectroscopy, details of which can be found elsewhere in this encyclopedia.

Circularly Polarized Components

LPL can also be considered as being composed of two in-phase equal magnitude CPL components, with their electric field vectors describing left- and right-handed helices, respectively, as in **Figure 5**.

If the left circularly polarized component were to be retarded relative to the right by a distance δ and then the components recombined, LPL would be regained but with a rotated plane of polarization; the angle or rotation (φ) being given by the relationship:

$$\varphi = \frac{\delta \cdot \pi}{\lambda}$$

Similarly, if the right CPL were to be retarded (a negative δ) a rotation of the plane in the opposite direction would be apparent, corresponding to an inversion in the sign of rotation. This is the basis of optical rotation, more of which can be found in the related sections in the encyclopedia, the retardation distance being given by the differential refractive indices of a chiral sample to CPL ($n_L - n_R$). Likewise, it is the basis of ‘half-wave plates’

that rotate plane-polarized light by 90° , but simply described from a different perspective.

However, suppose instead of retardation, the left circularly polarized component underwent a reduction in magnitude (such as when it is absorbed). Combining back with its right circular polarized complement, *elliptically polarized light* is obtained instead of the original linearly polarization. In terms of the amplitudes of the two circularly polarized components (P_L and P_R , respectively), the ellipticity defined earlier in the text is now given by

$$\tan \theta = \frac{P_R - P_L}{P_R + P_L}$$

and, in terms of their intensities I_L and I_R :

$$\tan \theta = \frac{I_R^{1/2} - I_L^{1/2}}{I_R^{1/2} + I_L^{1/2}}$$

Differential Absorption and Light Intensities

To measure CD, a CD spectrometer invariably generates both hands of CPL from plane-polarized light and, in some way, measures the difference in absorption of each by a sample. By scanning or delineating the wavelengths of light, a CD spectrum is acquired, that is,

$$\Delta A_\lambda = A_{L\lambda} - A_{R\lambda}$$

Figure 5 (a) (Top) linearly polarized light of wavelength λ , polarized in the vertical plane, showing the electric field vectors perpendicular to the direction of propagation through space; (b) (bottom) the light decomposed into two in-phase components with left and right circular polarizations, respectively. From Chiralabs Ltd., with permission.

where ΔA_λ is the CD at wavelength λ , with $A_{L\lambda}$ and $A_{R\lambda}$ being the absorption of left and right CPL of wavelength λ , respectively. The mean (unpolarized) absorption, A_λ , can similarly be defined by

$$A_\lambda = (A_{L\lambda} + A_{R\lambda})/2$$

By far the most commonplace CD measurements are by transmission of light through a sample; although reflectance CD can be measured, indeed it extremely diagnostic in some cases (e.g., the diffuse reflectance CD investigations of Tranter, Le Pevelen and Wolstencroft), its measurement can be fraught with difficulties arising from linear dichroism artifacts for the unwary.

As a practicality, instruments actually detect light intensities (or photon counts) rather than absorptions, with the relationships at a given wavelength:

$$A_{L\lambda} = \log \frac{I_{L0\lambda}}{I_{L\lambda}}$$

$$A_{R\lambda} = \log \frac{I_{R0\lambda}}{I_{R\lambda}}$$

$$\Delta A_\lambda = \log \left| \frac{I_{L0\lambda}}{I_{L\lambda}} \cdot \frac{I_{R\lambda}}{I_{R0\lambda}} \right|$$

where $I_{L0\lambda}$ is the intensity of the left CPL in the absence of the sample and $I_{L\lambda}$ that in the presence of a sample

through which the light has been transmitted; similarly for $I_{R0\lambda}$ and $I_{R\lambda}$ regarding right CPL. Typically, the intensity of the left and right CPL in the absence of the sample is taken as equivalent, whereupon

$$\Delta A_\lambda = \log \frac{I_{R\lambda}}{I_{L\lambda}} \quad \text{for } I_{L0\lambda} = I_{R0\lambda}$$

In virtually all cases, the CD signal, that is, the difference in absorption, is much smaller than the average absorption; concomitantly, the measured difference in light intensities between left- and right-handed CPL is typically small compared to the overall light intensity. As a consequence, the measurement of CD is invariably a more challenging task, more prone to noise and artifacts, compared to the equivalent measurement of average unpolarized absorption. It is not uncommon for the difference in absorption to be of the order of 10^{-6} that of the net absorption, a ratio that is conveniently described in general by Kuhn's dissymmetry factor 'g.'

$$g_\lambda = \frac{\Delta A_\lambda}{A_\lambda}$$

As a consequence, CD measurements are invariably more time consuming and require greater spectroscopic care than analogous unpolarized measurements.

Circular Dichroism versus Ellipticity

Although defined in terms of absorptions, CD can equally be described as an ‘ellipticity,’ (imagining the left and right circularly polarized beams were combined into one) as defined earlier in the text. Indeed, many CD spectrometers give their primary output in ellipticity units. Fortunately, it is trivial to convert between ellipticity and CD. Formally, from the definitions of ellipticity and CD in terms of light intensities:

$$\tan \theta = \frac{10^{\Delta A/2} - 1}{10^{\Delta A/2} + 1}$$

When the CD (or ellipticity) is small, this can be simplified to

$$\theta(\text{radians}) = \left(\frac{\ln 10}{4} \right) \cdot \Delta A$$

or, in more convenient degree units

$$\theta(\text{degrees}) = \left(\frac{180 \cdot \ln 10}{4\pi} \right) \cdot \Delta A$$

which gives the common conversion factor:

$$\theta(\text{degrees}) = 32.982 \Delta A$$

Instrumental Design

A CD signal can be determined by either measuring the difference in absorption directly, that is, ΔA (or correspondingly I_R/I_L), or by measuring each absorption alone, that is, A_L and A_R separately (or correspondingly I_L and I_R) and then calculating the difference (ratio). The design of commercial CD instruments thus fall into two basic classes, those that pass left and right CPL alternately through a sample, (single-beam design) and those that pass both simultaneously (dual-beam design). The two methods each have their advantages and disadvantages, as will be discussed below. In both cases, an unpolarized absorption spectrum can also be determined simultaneously to aid interpretation.

As a further alternative, it is possible to pass unpolarized or LPL through the sample and deconstruct the light into circularly polarized components (of unequal intensity) post sample. Such approach is found in ellipsometry and research instrumentation employed for specialist tasks, for example, planetary/astronomical spectrometry; such approaches are not elaborated further here.

Stray Light and Signal/Noise Limitations

As with many optical spectroscopies, two factors limit instrumental performance: first the faithfulness of the

result and second the ease at which a result may be obtained. In CD spectrometers, the former of these is crucially affected by the stray light performance and the latter by the signal-to-noise ratio.

Although the sources of stray light are similar to that found in unpolarized absorption spectrometers (and the reader is referred to such sections in the encyclopedia for further details), stray light in a CD measurement can have a dramatically greater effect than in an unpolarized absorption measurement, as its intensity is much more significant compared to the CD intensity *difference* than when compared to the average intensity. As a consequence, considerable effort is often expended in ensuring stray light is minimized.

Likewise, the signal-to-noise ratio is a limiting factor in the practical acquisition of spectra and, all other things being equal, can in general be related to the product of three factors:

$$\frac{\text{Signal}}{\text{Noise}} \propto \sqrt{IQ\tau}$$

where I is the intensity of the light impinging on the sample, Q is the efficiency (cf. photon efficiency) of the detector, and τ is the time span of the data acquisition. Again, with the CD signal being relatively small, the choice of light source and detector is crucial in ensuring that the time span of the acquisition is viable to achieve meaningful results.

Single-Beam Design

Figure 6 depicts the typical layout of the optical components of a commercial single-beam CD instrument, in which the light is directed from the source, through a monochromator to select wavelengths and impart a partial linear polarization, then through a linear polarizer to impart a high degree of linear polarization, then through a PEM to convert the light to circular polarization (rapidly alternating between left and right CPL), and then through the sample and onto a detector. Coupled to this optical layout is a phase lock-in amplifier that correlates the action of the PEM with the output of the detector to extract the CD signal. The details of each element of the instrument are described in the following text.

Light Source

Owing to the smallness of CD differential intensity, the influence of photon noise would be prohibitive unless a high-intensity source is employed. Commonly, a Xenon arc lamp of 150–450 W power is used, encapsulated within a quartz envelope for use in the far-UV region. Such arc lamps give high-intensity continuous light over

Figure 6 General optical layout of a typical single-beam circular dichroism spectrometer, with light source, monochromator prisms (P_1 , P_2), slits (S_1 , S_2 , S_3), polarizer (Pol), photoelastic modulator (PEM), sample, and detector identified. Light is directed by high-quality concave mirrors. The vertically and horizontally polarized light emanating from the monochromator are identified as ‘E’ and ‘O,’ respectively. From Chiralabs Ltd., with permission.

a broad wavelength range spanning 175–800 nm. The smaller sources of these arcs can be efficiently air cooled, but the larger sources require water cooling for safe operation. Even smaller sources may be employed in low-specification instruments or for specific tasks, such as chromatography detectors where high-quality spectra are not generated.

In extreme instruments, synchrotron radiation sources can be used that yield very high intensities and very short wavelengths. In these circumstances, care has to be taken due to potential photodegradation and local heating of samples (and optical components!).

Monochromators

A high-quality monochromator with very low stray light is a prerequisite for accurate CD determination. In most CD instruments, the wavelengths of light are selected by a prism-based double monochromator in a Czerny–Turner configuration, as depicted in **Figure 6**. Compared to diffraction gratings, quartz prisms are generally more efficient in the far-UV and have the important advantage of not generating higher-order diffractions, which contribute to the stray light of diffraction grating-based monochromators. Moreover, if crystalline quartz prisms are employed an added advantage of linear polarization of the light beam in the horizontal plane is obtained due

to the birefringence of the quartz. To minimize stray light but maximize polarization, the first prism has its optic axis aligned horizontally in the direction of the incident light (thus giving minimal birefringence), with the second having its optic axis vertical to maximize birefringence. In **Figure 6**, the ordinary (O, horizontally polarized) and extraordinary (E, vertically polarized) rays emanating from a crystalline prism-based monochromator are marked, the extraordinary ray being discarded (absorbed) within the monochromator. If fused prisms are instead employed, then subsequent linear polarization with a Rochon prism, etc. is typically required.

However, although the use of prism monochromators is desirable, they bring additional complications in terms of operation. Prism dispersion is nonlinearly wavelength dependent, unlike the constant dispersion of gratings. The slits of a prism-based monochromator have to be widened with reducing wavelength to achieve a constant spectral bandwidth. This is typically achieved by either a mechanical cam or electronic control.

Polarization and the Photoelastic Modulator

The light emerging from the monochromator is typically further linearly polarized so as to ensure the light impinging on the PEM is of high-purity linear polarization. If the light has already been linearly polarized by a prism

monochromator, then this may simply consist of a series of transparent plates oriented at Brewster's angle to maximize transmission of pure horizontally polarized light while reflecting vertically polarized light. However, if the light is not of sufficient linear polarization then a linear polarizing Rochon prism or similar optic may be inserted.

The heart of a CD spectrometer is the PEM; this device converts the LPL into CPL. It essentially consists of a transparent optical element that becomes birefringent under mechanical stress, such that it can alter the polarization properties of any light passing through it; for CD instruments, it is common for the optic element of the PEM to be fused silica. The stress is applied by a transducer attached to the optical element that undergoes the reverse piezoelectric effect, that is, generates stress when a voltage is applied to it. By applying an appropriate voltage, the transducer is stressed (expands or contracts) and, in turn, stresses the optical element, which alters its birefringence and thus alters the nature of the light transmitted through it. The construction of a PEM is illustrated in **Figure 7**.

Invariably, the optic axis generated is arranged to run the length of the transducer-optic composite, and the PEM module is oriented such that the impinging LPL has its polarization at 45° to the optic axis. The impinging light can then be thought of as being composed of two orthogonal components of equal magnitude: one that is parallel to the optic axis and other that is perpendicular.

By applying an appropriate voltage, the birefringence can be made such that it retards the component parallel to the optic axis by a quarter wavelength compared to the perpendicular component (i.e., it acts as a 'quarter wave plate'); in so doing, it generates left CPL. By reversing the voltage, the opposite effect is elicited and right CPL is generated. However, the birefringence is also wavelength dependent and, thus, to obtain circular polarization it is necessary to program the correct voltage for the wavelength of light being transmitted. Thus, the PEM voltage has to be carefully linked to the monochromator during scanning of wavelengths.

In practice, the voltage is applied sinusoidally at a frequency corresponding to the mechanical resonance frequency of the device. This ensures a degree of efficiency and stability of operation while generating large birefringence and cycling between left and right circular polarizations rapidly, typically of the order of 50 kHz. However, as the voltage is applied sinusoidally rather than as a square wave, all elliptical polarization states between linear and circular are generated at some time point in the cycle. Indeed, alternating orthogonal *linear* polarizations can be generated with higher voltages (by producing half-wave plate like behavior), allowing CD instruments to be adapted for linear dichroism measurements – albeit with greater likelihood of overstressing the PEM.

As might be expected, the PEM is a particularly delicate component of CD spectrometers and must be

Figure 7 Illustration of a photoelastic modulator (PEM), converting linearly polarized light (polarized in a plane at 45° to the PEM optic axis) into CPL as it passes through the optical element and a voltage (V) is applied to the transducer. From Chiralabs Ltd., with permission.

handled with considerable care. Moreover, it can be sensitive to thermal variations and is thus a source of error if the instrument has not been stabilized before data acquisition. Deterioration of the delicate mounting of the PEM optical element and transducer in older instruments can give rise to notable artifacts in spectra.

Sample Compartment and Attachments

Solution studies are typically carried out with the sample held within a fused quartz cuvette (cell). Many variants are available, including those of rectangular and cylindrical construction, thermostated flow cells, micro cells, and a plethora of specialist types. In particular, cylindrical cells with path lengths from 0.001 to 10 cm are readily available from commercial sources, allowing the study of a wide range of sample concentrations and quantities while avoiding problems of excessive or too little absorption. Whatever the cell construction, for reliable results, cells must be located in a fixed, reproducible orientation and position in the sample compartment.

Instrument manufacturers provide a wide range of attachments for controlling the sample, such as thermostated cell holders, stirrers, sippers, and cell auto-changers. As a minimum, the cell should at least be thermostated for most studies and bespoke cell holders that are temperature controlled by either recirculated water or Peltier devices to achieve this are popular.

Beyond such relatively simple attachments, manufacturers provide a welter of alternatives, including cryostats for low-temperature work, microfocusing attachments for minute samples, solid holders for solid-state transmission studies, high-pressure cells for chromatographic detection and hyphenation (e.g., HPLC-CD)

Detector

To detect the CD signal, the output of the detector is correlated with the cycling of the PEM by a phase lock-in amplifier to specifically extract (in an ideal world) the oscillating signal, corresponding to the switching between left and right circular polarizations. The resonance frequency of PEM, typically 50 kHz, necessitates a fast responding detector, which together with the requirements of high efficiency and accuracy, have ensured that photomultiplier tubes (PMT) have been the detector of choice for decades.

In operation, a PMT generates a current that is related both to the intensity of light impinging on it and to the accelerating voltage applied. In a typical implementation within a CD spectrometer, the voltage applied to the detector (often referred to as the HT: the 'high tension' voltage) is varied so as to endeavor to keep the current generated constant. Thus, the higher the light

intensity falling on the detector, the lower the voltage needed to maintain its set output current. The voltage required can thus be monitored to determine the light intensity and, *inter alia*, the net absorbance of the sample.

Assuming a sample is chiral and generating a CD signal then, as the PEM oscillates between transmitting left and right CPL, so the intensity of the light falling on the detector will likewise since one component of light is absorbed more than the other by the sample. Consequently, the response of the detector will likewise oscillate. By measuring the magnitude of this oscillating signal, with the aid of a phase lock-in amplifier, the value of the CD signal can be determined.

Recently, advances in photodiode technology have resulted in new, high-gain, large-area solid-state detectors, which provide improvements in quantum efficiency across the UV, visible, and near-infrared wavelength ranges and are now being employed in a range of CD instruments. Such detectors potentially have greater efficiency than standard PMTs and may hold the promise of better signal-to-noise ratios and thence faster acquisition times, although these have yet to fully supersede PMTs.

Dual-Beam Design

The essential design difference of a dual-beam CD spectrometer, for example, popularized by the Olis range (which have both prism and diffraction grating monochromators), is that both the ordinary and extraordinary LPL beams are allowed to be transmitted through the PEM. With the appropriate geometry, this generates two circularly polarized beams, one left handed and the other right handed, slightly spaced apart and diverging. By passing both through the sample simultaneously and independently detecting each, the two absorptions (or light intensities) can be determined directly and the difference (or ratio) calculated to give the CD. As the PEM is oscillating, the handedness of the two circularly polarized beams actually swap at the oscillating frequency, providing a further correction for any mismatches between the beams. Since the CD is determined by the response of two detectors simultaneously, the need for phase lock-in amplification is essentially removed.

In principle, this elegant approach provides a means of measuring CD with less reliance on CD intensity calibration, although the drawback is that the two beams do not exactly coincide and thus the absorptions and thence CD is not for an identical portion of the sample. For heterogeneous samples this may prove troublesome, although the PEM beam handedness swapping may mitigate against this. The dual-beam approach is currently being used for the CD beamline of the Diamond Synchrotron facility (Oxfordshire, UK).

Instrumental Operation

Calibration and Testing

The two axes of a CD spectrum, namely the wavelength and the CD, dictate that these two scales of an instrument be calibrated. To calibrate wavelength it is typical to inspect the unpolarized absorption spectrum, or the HT voltage 'spectrum' of the PMT detector of the instrument. The wavelength scale calibration is typically accomplished by the use of either a series of line emissions from discharge lamps, the precise wavelengths of which have been tabulated, or through standard filters with known absorption spectra. For general convenience, the filter method is the one of choice. The most common filters used are those of holmium or didymium (a mixture of neodymium and praseodymium) oxide in glass. However, these can be difficult to produce consistently and can show variations of some ± 4 nm in peak positions at the long wavelength end of their useful range (240–685 nm). Therefore, for accurate calibration, it is necessary to use filters provided with a table of determined peak positions from a reputable source such as a national laboratory for standards. As an alternative to glasses, solutions containing lanthanide ions have proved useful, with less variation but a corresponding decrease in convenience.

The calibration of the CD magnitude is more troublesome. Conventionally, a solution of a chiral substance with a well-established CD spectrum, at an accurately known concentration, is employed and the instrument adjusted until the correct CD at the calibration wavelength is achieved. As CD is often temperature sensitive, the calibration must be performed with the calibrant thermostated within the instrument.

Ideal requirements for such a calibrant include a large inherent and well-defined CD spectrum combined with a low molar absorption (to allow a well-defined CD signal to be measured without stray light complications), adequate solubility, good stability, nonhygroscopic, and available with high purity.

The most popular choice for this has historically been either d-10-camphorsulfonic acid (alas deliquescent) or, more conveniently, ammonium d-10-camphor sulfonate (ACS), specially purified for this task. ACS has a large characteristic broad CD signal centered at 290.5 nm with a miniscule absorption. Alternatives include D-(–)-pantolactone, which has a characteristic CD at approximately 219 nm, as originally proposed by Konno in 1975. Since the late 1960s various transition metal complexes have also been employed as calibrants on occasions, including *tris*(ethylenediamine), cobalt (III) complexes (DeTar, Tsujimura, Schippers-Dekkers, Norden), and nickel (II) tartrate (Konno). On the basis of Stephen Mason's pioneering work, the author (Tranter) has personally employed a variety of transition metal and lanthanide

complexes as secondary standards (together with ACS) since the 1980s, these possessing useful, multiband CD spectra with low absorptions due to their d-d or f-f transition nature.

New alternatives continue to be sought, as but yet ACS has not been superseded as the primary standard. Mechanisms for calibrating across multiple wavelengths, indeed the complete wavelength range of an instrument, rather than at just a single wavelength, are under development.

As well as ensuring wavelength and CD magnitude accuracy, the instrument should be checked regularly for signal-to-noise performance and slit width (spectral bandwidth) fidelity. Xenon arc lamps have a limited life span, and noise will become more evident as the photon flux of an aging arc diminishes. The absolute testing of spectral bandwidths and slit widths is challenging; however, a quick evaluation for consistency can be achieved by comparing the apparent baseline 'absorption' spectra (i.e., in the absence of a sample) across the complete wavelength range for a series of spectral bandwidths ('Tranter's humpback whale test'...). The relationships between spectra of the series are diagnostic of slit errors. If the slits are functioning correctly, the apparent absorption spectra should all follow the same pattern, but simply shifted from each other by a wavelength-independent value related to the logarithm of the ratio of spectral bandwidths and the number of slits in the monochromator affecting the spectral bandwidth.

Operation and Methodology

In all cases, flushing of spectrometers with inert nitrogen is good practice to ensure their maintenance in a high-quality state and avoid ingress of any deleterious airborne contaminants. However, it is imperative for CD instruments operating in the UV wavelength region; UV light generates ozone from oxygen that is harmful both to the operator and the instrument, as well as giving undesired absorptions in the far-UV. The instrument should, therefore, be flushed with copious high-purity nitrogen (such as obtained from evaporated liquid nitrogen) while in operation and, ideally at all times. As a consequence, the hazard of oxygen depletion in a laboratory should be assessed. In rare cases, for vacuum-UV wavelength region work, instruments have been designed to be under vacuum, which negates the need for flushing but clearly introduces considerable other constraints on instrument design.

As with all spectroscopies, it is important to ensure instrumental parameters are chosen appropriately for the study in hand. The wavelength resolution of a spectrum is governed primarily by the spectral bandwidth of the instrument, as determined by the monochromator slit

width. If the spectral bandwidth is chosen too large, the spectral features will be broadened and distorted, and if it is too small then, while the spectrum will be faithful, the acquisition will take longer to achieve a given signal-to-noise ratio due to the lower light intensity being transmitted by the monochromator. As a general rule, to obtain a faithful representation of a spectrum at least 10 reliable datapoints should be acquired over a spectral peak. This immediately requires that the *spectral bandwidth of the instrument be set at least smaller than one-tenth of the width of the narrowest spectral feature of interest*. Typically, for UV and visible CD, this would require a 1-nm spectral bandwidth unless particularly narrow or broad features are under investigation.

Modern instruments can typically acquire a spectrum versus wavelength in two ways: by either ‘continuous scanning,’ that is, continuously varying the wavelength while accumulating data, or ‘step scanning,’ that is, stepping to a wavelength position, accumulating data there for a set period of time, and then stepping to the next wavelength position and so on. If a continuous scan mode is employed, it is crucial that the scan speed is not set too fast compared to the instrument response time such that the spectrum becomes distorted. As a *general ‘golden rule,’ for continuous scanning*:

$$\frac{\tau(\text{sec}) \cdot \text{ss}(\text{nm}/\text{min})}{60} < \text{SBW}(\text{nm})$$

where τ is the response time (in seconds), ss is the scan speed (in nanometers per minute) and SBW is the spectral bandwidth in nanometers. The use of too fast a scan speed for the chosen response time will give spectra with apparently less noise, but this is an illusion resulting from the ‘smearing’ of the frequency-limited noise; the spectral features will also typically be flattened and broadened. Suggested values for most circumstances are a response of 4 s, scan speed of 10 nm min^{-1} and a spectral bandwidth of 1 nm. If the step-scanning mode is used, these concerns are eliminated, but care must still be exercised not to step at a rate faster than the instrument can reliably achieve.

Frequently, multiple spectra will need to be accumulated to achieve acceptable signal-to-noise ratios. Consistent with the signal-to-noise relationship given earlier, the signal-to-noise ratio will follow the proportionality:

$$\frac{S}{N} \propto \sqrt{\tau \cdot \text{acc} \cdot \text{SBW}^n}$$

where τ is the response time or averaging time (for continuous and step scanning, respectively), acc is the number of accumulations, SBW is the spectral bandwidth,

and n is the number of slits in the monochromator affecting the SBW. As can be seen, increasing the response time or number of accumulations suffers from diminishing returns due to the square root relationship.

As with other absorption-based optical spectroscopies, the solutions should generally be prepared with minimal particulates present, to minimize scattering artifacts, with solvents chosen to have minimal absorption in the wavelength region of interest. For optimal signal-to-noise ratio, the unpolarized absorption of the sample, at the wavelength of interest, should be ≈ 0.84 AU, but between 0.4 and 1.3 AU is usually adequate. A higher absorption causes too few photons to reach the detector, such that the signal-to-noise ratio deteriorates badly and, moreover, stray light effects begin to confound the spectrum (typically above 1.6 AU is catastrophic); this is often accompanied with the voltage being applied to the PMT becoming excessive for faithful detection ($>700 \text{ V}$). However, a lower absorption than this range will often necessitate a lengthy acquisition time unless the sample has a particularly large CD signal. The absorption can be manipulated by either changing concentration or, often more conveniently, changing cell path length accordingly.

In virtually all cases, a sample spectrum should be corrected by the subtraction of a baseline spectrum of the solvent acquired under equivalent conditions (same cell) at a proximal time. Moreover, to gain the maximum benefit from the instrument, both the CD and unpolarized absorption spectrum should be inspected. In the case of comparing spectra run in substantially different solvents, it may be advisable to consider implementing a Lorentz correction for the solvents.

The measurement of the usually small net circular polarization in the luminescence from chiral molecules began with the pioneering studies of Professor L.J. Oosterhof at the University of Leiden in the late 1960s. In more recent years this technique has developed into a reliable and useful spectroscopic tool for the study of a wide variety of chemical systems. The phenomenon has been referred to as circularly polarized luminescence (CPL), circularly polarized emission (CPE), and by other names. Here the most common acronym, CPL, is used to describe this experimental technique. The measurement of the differential emission intensity due to differences in the absorption of left versus right circularly polarized light is also discussed. This is commonly referred to as fluorescence-detected circular dichroism (FDCD). Whereas FDCD spectroscopy (like conventional circular dichroism (CD)) probes the chiral structure of the ground state, CPL is a probe of the chirality of the excited state. These types of experiments are not redundant, since changes of geometry do occur on electronic excitation. Furthermore, both of these experimental techniques provide information concerning molecular dynamics and energetics that occur between the time of excitation and emission.

Instrumentation for Measurement of Circularly Polarized Luminescence

CPL spectroscopy has been used for more than 30 years as a probe of the molecular stereochemistry of chiral

luminescent molecules and complexes. Unlike CD, CPL measurements have not, as yet, become routine. This is primarily due to the lack of a commercially available instrument until recently. The measurement of the generally small net circularly polarized luminescence, relative to the total luminescence, is difficult owing mainly to the presence of optical artefacts from various sources, and to electronic problems associated with the measurement of weak differential signals. The first CPL measurements were made using analogue phase-sensitive detection systems. Measuring the generally small CPL signal in this way is particularly difficult because of electronic problems associated with lock-in amplifiers. All of the current instruments use photomultipliers operating in photon-counting mode, and some type of gated photon counting system to determine the circular polarization. This is the type of system that will be described here.

Steady-State CPL

Due to the lack of commercial instrumentation, most CPL measurements that have been published have been measured on instruments that were designed and constructed in individual laboratories. The basic configuration of a system designed to measure CPL is given in **Figure 1**. A laser system or a UV lamp used in combination with an excitation monochromator or a combination of filters can be used as the exciting source. Care should be taken in ensuring that the polarization of the excitation light is such that there will be no linear polarization in the emission since this is known to cause artefacts in the detection of circular polarization. In most luminescence experiments the emission is collected at an angle of 90.0° from the direction of the excitation beam to avoid detecting light from the excitation source. In some applications of CPL spectroscopy, it is necessary to control the excitation polarization. **Figure 1**, for example, shows the optics necessary to produce circularly polarized excitation.

The luminescence from the chiral sample is first directed through a photoelastic polarization modulator (PEM) and then a linear polarizer before it passes through any focusing lenses or filters because these optical components may be birefringent. The linear polarizer ensures that the detected light entering the monochromator will

Figure 1 Schematic diagram of an instrument designed to measure circularly polarized luminescence.

always be polarized in the same direction. This prevents artefacts associated with the emission monochromator being polarization sensitive. The PEM is composed of an isotropic, clear optical material that produces an oscillating birefringence at a fixed frequency. In CPL measurements, the PEM is operated as an electrically controlled advancing-retarding quarter-wave plate at a predetermined frequency (f). This introduces a periodic phase shift at frequency f , such that either right or left circularly polarized emitted light is converted to linearly polarized light oriented at 45° to the PEM crystal axis. Therefore, the PEM and linear polarizer allow the passage of alternately left then right circularly polarized light. The emitted linearly polarized light is then focused onto the entrance slits of an emission monochromator. Background signal from stray excitation and room light can be reduced by placement of a long pass filter in front of the monochromator. The light exiting the monochromator is detected by a photomultiplier tube operating in photon-counting mode. The signal from the photomultiplier tube is sent into an amplifier-discriminator. These devices are capable of providing simultaneous dual output for TTL pulses that are generated for photon spikes, as well as a voltage proportional to the total emission intensity.

The TTL pulses are analysed by a photon counter using the reference signal at frequency f to direct the pulses into two separate counters. The time dependence

of the phase shift imparted by the PEM is such that it is exactly quarter-wave retarding or advancing only at the maximum or minimum of the periodic oscillation. For this reason, it is common to select finite time-windows centred at the peak of the modulation cycle for the counting of photon pulses, and not to count the pulses in the 'dark' interval. Even when these windows are set to collect 50% of the incoming TTL pulses, only a slight error ($<5\%$) in the accuracy of this measurement is introduced. On alternate half-cycles of the modulation cycle, the TTL pulses are directed into two separate counters corresponding to the transmission of left (I_L) or right (I_R) circularly polarized light through the PEM. In CPL spectroscopy one commonly reports the ratio of the differential emission intensity at wavelength, λ

$$\Delta I(\lambda) = I_L(\lambda) - I_R(\lambda) \quad [1]$$

to the total emission intensity.

$$I(\lambda) = \frac{1}{2}(I_L(\lambda) + I_R(\lambda)) \quad [2]$$

We thus define the luminescence dissymmetry ratio, g_{um} , as follows:

$$g_{\text{um}}(\lambda) = \frac{\Delta I(\lambda)}{\frac{1}{2}I(\lambda)} = \frac{I_L(\lambda) - I_R(\lambda)}{\frac{1}{2}(I_L(\lambda) + I_R(\lambda))} \quad [3]$$

I , ΔI , and g_{lum} may all be calculated from the values of the two counters. Because of the difficulty in determining absolute emission intensities, it is most common to report CPL results in terms of g_{lum} .

Calibration and Standards

The determination of the precise state of polarization of the circularly polarized emission, and of the accuracy of a gated photon-counting system, may be accomplished by a number of methods. The simplest and most convenient approach for calibration is to use a standard to measure g_{lum} . For example, several groups have used the chiral and commercially available NMR shift reagent tris (3-[trifluoromethyl-hydroxymethylene]-*d*-camphorato) europium-(III) (Eu(facam)₃; Aldrich) in dry dimethyl sulfoxide (DMSO). This calibration can be performed by exciting the solution of Eu(facam)₃ in the visible or ultraviolet, and measuring g_{lum} at several different wavelengths. This complex has known g_{lum} values of $+0.072$ at 612.8 nm for the strong emissive transition $^5D_0 \rightarrow ^7F_2$, and -0.78 for the $^5D_0 \rightarrow ^7F_1$ transition at a wavelength maximum of 595 nm. Calibration of the gated photon counting system could also be accomplished by passing completely left and right circularly polarized light through the PEM. This should in theory yield g_{lum} values of $+2$ and -2 , respectively. However, the value of exactly 2 (or -2) is never obtained owing to imperfect circular polarization and the inaccuracies associated with the finite time-window for the gated photon counter, as described above.

One of the main advantages of the photon-counting system over lock-in detection is the fact that, if the instrument is working properly, i.e. obeying Poisson photon statistics, then it can be shown that the distribution of measured g_{lum} values should obey a Gaussian distribution. It can also be shown that the standard deviation in g_{lum} is equal to the inverse square root of the total number of photon counts:

$$\sigma = \sqrt{\frac{1}{N}} \quad [4]$$

Measuring a large number of g_{lum} values and seeing whether the distribution is Gaussian is another convenient way of checking whether the instrument is working properly.

The intensity of luminescence will obviously vary greatly from one sample to the next. Some samples will be highly luminescent (i.e. give high count rate) while others will be weakly luminescent (i.e. give low count rate). For samples that are highly luminescent, accurate g_{lum} measurements can be achieved in a short time. For example, if a sample is emitting 10^6 photons s^{-1} , then using eqn [4], g_{lum} with a standard deviation of 10^{-4} requires 100 s to be measured. Weakly luminescent

samples require much longer collection times to achieve the same standard deviation. If the count rate is only 10^4 photons s^{-1} , then more than 5 h of data collection are required.

Time-Resolved CPL

Advances in digital counting technology and high-speed computers have allowed several research groups to expand the measurement of CPL into the time domain. These advances have been led by the research groups of Professor H.P.J.M. Dekkers at the University of Leiden and Professor F.S. Richardson at the University of Virginia. The instruments used are based on modifications of steady-state instruments such as the system described above, with the major instrumental change being that the excitation source must be pulsed. The principal problem in time-resolved CPL is how to measure the decay of the polarization with an instrument based on a polarization modulator that may be oscillating much more rapidly than the lifetime of the decay. Two approaches to this problem have been successful. If the precise phase of the polarization modulator is known, then an excitation pulse can be coordinated with the periodic oscillation in such a way that the flashes occur at precise times in both halves of the modulation cycle. To ensure that the device is analysing for circular polarization at each decay point, the time between the excitation and the decay measurements is varied. Just as described above, for each finite time interval centred at time t in the decay, photon pulses corresponding to $I_L(t)$ and $I_R(t)$ are accumulated, and by simple calculation, $g_{\text{lum}}(t)$ is determined. Alternatively, it is possible to completely decouple the excitation flashes from the modulation cycle and accumulate enough flash events that the complete modulation cycle is sampled for every finite time channel. This latter method has the advantage that the complete time decay for each excitation pulse contributes to the measurement.

Applications for Circularly Polarized Luminescence

The applications of this spectroscopic technique have predominantly been limited to the study of specific research goals of those groups who have built an instrument. Nevertheless, the applications have covered a fairly wide area of chemistry, including organic, inorganic, polymer and biochemical systems. It should be mentioned that most applications of CPL have involved forbidden spectroscopic transitions. This is because, in these experiments, one is always measuring small differences in luminescence intensity. These differences are obviously easier to detect if the individual intensities

themselves are not very large, i.e. if they are not associated with allowed transitions.

This section highlights examples of different kinds of applications, and the reader is referred to one of the review articles listed in the Further Reading section for a more detailed discussion of specific chemical systems in which CPL has been used.

Applications to Organic Chromophores

Many of the early applications of CPL involved analysis of the circular polarization from $^1n\pi^*$ states of chiral ketones. Pyramidal distortion of the $>C=O$ group upon going from the ground state to the excited/emitting state in CD spectroscopy is well known, and comparative CD and CPL studies have been used to probe these excited state geometry changes. As an example, **Figure 2** shows the CPL spectrum (upper curve) and total luminescence spectrum (lower curve) for an α -diketone, *d*-camphorquinone dissolved in ethanol. Note that the form of presentation of CPL results parallels that usually seen for CD studies. In this example, the luminescence dissymmetry ratio, g_{lum} , at the peak maximum for this $n \leftarrow \pi^*$ transition is approximately -0.01 . g_{abs} measured from the CD spectrum of this compound for the $n \rightarrow \pi^*$ transition is approximately -0.009 , and the differences between these measurements reflect geometry changes within the dicarbonyl moiety upon electronic excitation.

Figure 2 CPL spectrum (upper curve) and total luminescence spectrum (lower curve) for *d*-camphorquinone in ethanol.

In bichromophoric molecules one may use the well-known exciton coupling model to interpret CPL results in exactly the same way that this model is applied to CD measurements. In a very few cases, for example, β,γ -enones, chirality rules have been developed that relate the sign and magnitude of the CPL signal for closely related compounds to specific aspects of chiral structure. These attempts at spectra–structure correlations are clearly not as well developed as they are for CD spectroscopy.

Inorganic Applications

As described above, CPL spectroscopy is particularly suited for the study of forbidden transitions, so the potential for applying this technique to intraconfigurational transitions in metal complexes is very high. In the case of transition metals, however, applications of CPL have been quite limited. The reasons for this are many. Certainly, the preparation of resolved chiral transition metal complexes is quite difficult, and often the racemization under UV or visible illumination may not be neglected. In addition, not many transition metal complexes are luminescent in liquid solution. The luminescence from ‘frozen’ samples can be quite high, but measurement of CPL under conditions where the sample is highly scattering and nonisotropic is fraught with experimental difficulties. There have been a number of interesting applications of CPL to chiral transition metal complexes. For example, $Ru(1,10\text{-phenanthroline})_3^{2+}$ may easily be prepared and resolved. This compound possesses D_3 symmetry and, as such, exists as Δ and Λ enantiomers. The broad luminescence from this complex centred at 600 nm under UV excitation is fairly intense with a measured g_{lum} value of approximately 0.0007. g_{lum} varies significantly in the low-wavelength shoulder of the emissive transition, indicating that the precise nature of the metal–ligand states involved are quite complicated. There have also been a few examples of CPL measurements from crystalline samples; however, the requirements here are that the sample be chiral and luminescent, and occur in a space group that is uniaxial. This combination is very restrictive.

By far the most common class of inorganic compounds that have been studied by CPL spectroscopy are luminescent lanthanide complexes. There are several reasons for this special interest. Complexes of Tb(III), Eu(III) and, to lesser extent, Dy(III) are luminescent in the visible region of the spectrum, particularly if water molecules can be excluded from the first coordination sphere. The transitions involved are isolated $f \leftrightarrow f$ transitions, and even though the absorptions are very weak, all three of these ions have absorptions in the visible, which overlap convenient strong laser lines. In many cases it is also possible to excite allowed transitions in the ligand orbitals, and populate the lanthanide ion energy levels through

efficient energy transfer. Lastly, and most importantly, the states derived from the various *f*-electron configurations are well characterized by the total angular momentum quantum number *J*, and transitions that obey magnetic dipole selection rules, that is $\Delta J = 0, \pm 1$, are often associated with very large dissymmetry ratios.

An example of CPL from a chiral lanthanide complex is given in **Figure 3**. This spectrum was obtained by exciting the sample of the macrocyclic Tb(III) complex with 488 nm excitation from an argon-ion laser. The spectral region displayed corresponds to a transition from the 5D_4 excited state to the 7F_5 state in the ground-state manifold. This transition satisfies the magnetic dipole selection rules introduced above. The ground state for Tb(III) is the 7F_6 state. The various peaks shown in the spectrum correspond to different crystal field transitions within the term-to-term transition. The chiral pendant amines in the macrocyclic ligand are chiral, and this results in only one of the possible C_4 orientations around the central metal ion being formed. Confirmation of this latter conclusion may be obtained by varying the incident polarization from left to right circularly polarized, and the result for this system is that no effect is seen in the CPL spectrum. As can be seen in **Figure 3** $|g_{lum}|$ for magnetic dipole-allowed transitions may be very large. The values seen in **Figure 3** approach 0.4; this should be compared to the results presented in **Figure 2** (0.01),

which represents approximately the maximum value that has been measured for organic chromophores.

Unlike transition metal compounds such as $Ru(phen)_3^{2+}$, which are composed of achiral ligands but can be resolved into chiral enantiomers, the resolution of chiral lanthanide compounds with achiral ligands is much less amenable. This is because lanthanide complexes are generally more labile than transition metal complexes. Just like transition metal complexes, however, it is possible in some cases to perturb the ground-state equilibrium concentration through the addition of a chiral environment compound. This is sometimes referred to as the Pfeiffer effect. An example of such an experiment is presented in **Figure 4**. In this experiment, D- and L-enantiomers of glucose have been added to aqueous solutions of Tb(2,6-pyridinedicarboxylate) ($Tb(DPA)_3^{3-}$). This complex is known to possess D_3 symmetry, so it occurs in solution as a mixture of Δ and Λ enantiomers.

Racemic Mixtures

Even though the ground-state distribution of a mixture of chiral molecules is racemic, in some cases it is still possible to measure the CPL if the excited state can be enriched in one of the enantiomers. If, for example, the excitation beam is circularly polarized, one of the enantiomers will be excited preferentially over the other, and

Figure 3 CPL spectrum (upper curve) and total luminescence spectrum (lower curve) for an aqueous solution of a chiral macrocyclic Tb(III) complex.

Figure 4 CPL spectra and total luminescence (lower curve) for an aqueous solution of $Tb(DPA)_3^{3-}$ containing 0.01 M D-glucose (upper curve) and L-glucose (middle curve).

the excited state will not be racemic. This experiment, which has been referred to as CPE/CPL, relies on discrimination in absorption and emission. Obviously, it is also important that the nonracemic excited-state distribution created by the excitation beam is maintained during the excited state's lifetime. An example of such an experiment is given in **Figure 5**. The CPL spectrum given in **Figure 5** was collected while exciting an aqueous solution of $\text{Eu}(\text{DPA})_3^{3-}$ with circularly polarized 472.8 nm light from an argon-ion laser. These complexes do not racemize on the emission timescale, so one may write down the following equation relating the measured luminescence dissymmetry ratio for left circularly polarized excitation to the intrinsic absorption and emission dissymmetry ratio for one of the enantiomers as follows:

$$g_{\text{lum}}^{\text{L}}(\lambda) = \frac{1}{2} g_{\text{abs}}^{\text{A}}(\lambda') g_{\text{lum}}^{\text{A}}(\lambda) \quad [5]$$

In this equation we have been careful to denote that the wavelength of excitation (λ') is different from the wavelength of emission detection.

Measurement of CPL from racemic mixtures is not a technique that can be applied to all racemic solutions. For moderately luminescence systems g_{lum} values of approximately 10^{-4} are measurable. This means that the intrinsic absorption and emission dissymmetry ratios need to be on the order of 10^{-2} for this experiment to be successful. Although there have been a couple of

examples using this technique in organic systems, by far the most widely studied systems are racemic lanthanide complexes, such as given in **Figure 5**, because of the large g_{lum} and g_{abs} values that may exist for certain $f \leftrightarrow f$ transitions. It is also useful to perform these experiments in a time-resolved mode and as a function of temperature to determine racemization rate constants.

There are other ways to generate enriched excited states from racemic ground states. If, for example, a chiral excited state quencher molecule is added to a racemic solution, the rate of quenching of the two enantiomers may be different. This kind of experiment has been performed both in the steady-state and time-resolved modes. At time $t=0$ following an unpolarized excitation pulse directed at a racemic mixture, the concentration of excited enantiomers will be equal. The diastereomeric selective quenching results in a time-dependent population that becomes increasingly richer in one of the enantiomers. Results from a typical experiment of this type are given in **Figure 6**. Here g_{lum} is plotted as a function of time for an aqueous solution of $\text{Tb}(\text{DPA})_3^{3-}$ into which a small amount of $\Delta\text{-Ru}(\text{phen})_3^{2+}$ has been added. The different quenching rates for the diastereomeric pairs depend in a complicated way on mutual diffusion, reorientation, electronic overlap and diastereomer structure. These types of experiments may be performed with varying donor-quencher pairs, in different solvents, and as a function of temperature and pressure to probe intimate details of this excited-state chiral discrimination.

Figure 5 CPL spectrum (upper curve) and total luminescence (lower curve) for an aqueous solution of $\text{Eu}(\text{DPA})_3^{3-}$ using circularly polarized 472.8 nm excitation.

Biological and Polymer Systems

Almost all biological systems are chiral, so it is natural to expect that CPL studies involving luminescent biological

Figure 6 Time dependence of g_{lum} at 544 nm following excitation at 330 nm for an aqueous solution of $\text{Tb}(\text{DPA})_3^{3-}$ into which a small amount of $\Delta\text{-Ru}(\text{phen})_3^{2+}$ has been added.

material will be important. Unlike CD, where all of the absorbing chromophores contribute to the resultant CD spectrum, luminescence from protein and other biological systems is generally only seen from a very small number of emitting chromophores. Thus, CPL studies involving biological systems generally only provide specific structural information localized around the emitting chromophore, and not the longer-range information on secondary and tertiary structure that is routinely obtained from CD studies. This is true both for intrinsic protein fluorescence and in studies in which metal ion or organic fluorescence probes are used.

Some of the very early applications of CPL spectroscopy involved chiral polymeric systems. In particular, the CPL from achiral dye molecules dissolved in cholesteric liquid crystals has been used to probe chirality changes. CPL from chromophores attached to a chiral poly-amino acid may also be used to study exciton coupling between aromatic chromophores. In these polymeric systems, it is often observed that g_{lum} is quite large. In some cases it is so large, in fact, that detection using static quarter-wave plates is possible.

Instrumentation for Measurement of Fluorescence-Detected Circular Dichroism

In fluorescence-detected circular dichroism (FDCD) the difference in total emission intensity is used to monitor differences in circularly polarized absorption. This spectroscopic technique was developed in the early 1970s in the laboratory of Professor I. Tinoco at the University of California, Berkeley. In the simplest application of FDCD a photomultiplier tube is placed at 90° to the direction of emission detection in a modified commercial or custom-built CD instrument and the luminescence intensity in phase with the oscillating left and right circularly polarized absorption beam is monitored. For many applications, including recent uses of FDCD as detectors in HPLC, this type of experimental setup is sufficient. The major technical challenge in the construction of an FDCD instrument is associated with the fact that it is very difficult to produce pure circularly polarized excitation without any residual polarization. Furthermore, if this linear polarization varies in phase with the incident circular polarization, serious artefacts may result. To reduce this problem, a somewhat more complicated experimental setup is required. A schematic diagram of an FDCD instrument designed to deal with the linear polarization problem is shown in Figure 7.

The incident (absorption) beam is wavelength-selected by an excitation monochromator and then converted to alternately left and right circular polarization by use of a

linear polarizer and quarter-wave modulator. The quarter-wave modulator may be a PEM as described above for CPL measurement, or a Pockels cell. This luminescence in phase with the incident polarization modulation is collected by two photomultiplier tubes (PMT1 and PMT2) oriented at right angles to each other and the incident beam. If the excitation is linearly polarized, then the sum of the fluorescence intensities from the two detectors due to this artefact gives a signal ($V_1 + V_2$) that is independent of the linear polarization. So even if this polarization changes as the incident polarization varies from left to right, the resultant artefact signal subtracts out of the difference in fluorescence intensity, $F_L - F_R$. The artefact signal does not subtract out of the total luminescence intensity, $F_L + F_R$, but, if present, it may be reduced by rotation of the PEM (or adjustment of the Pockels cell). The signals from the photomultiplier tubes are added and either these are input to a lock-in detector (as shown) or, if digital counting techniques are employed, the TTL pulses are analysed by a gated photon-counting system as described previously.

To relate the measurement of FDCD to conventional CD, it is necessary to take into account that, if differential absorption of the circularly polarized excitation beam is taking place, then the intensity of the absorption beam as a function of distance into the sample may be different for the two circular polarizations. The relationship between CD and FDCD measurements for isotropic systems containing only one optically active fluorophore

Figure 7 Schematic diagram of FDCD instrument.

may be expressed as

$$\Delta\varepsilon = \varepsilon_L - \varepsilon_R = \frac{g_F(1 - 10^{-A})}{cd10^{-A}\ln 10} \quad [6]$$

where A denotes the absorbance of the sample, c is the concentration, and d is the pathlength. Processing of FDCD signals under conditions where there are more than one chiral chromophore is more complicated. Calibration of an FDCD instrument may be accomplished by measuring the signal for an achiral fluorescent molecule to ensure that a value of zero is obtained, and then by measuring a standard compound with a known CD such as *d*-camphorsulfonic acid.

Applications of Fluorescence-Detected Circular Dichroism

FDCD measurements have the potential for providing valuable spectroscopic and structural information for systems in which conventional CD measurements are problematic. Of particular interest are complex systems containing multiple absorption chromophores but only one fluorescent chromophore. It is also possible to use the intrinsically higher sensitivity of luminescence detection to determine the CD of samples for which only very small quantities are available. FDCD has also shown promise in high-pressure liquid chromatographic detection of luminescent chiral molecules, although no commercial applications of this technology are yet available.

Some manufacturers of commercial CD instruments have long included in their range attachments to adapt

their instruments for FDCD spectroscopy. Although interesting and important applications for the FDCD technique have been undertaken, the technical problems associated with the generation of exactly equal intensities of circularly polarized exciting light, and the artefacts associated with residual linear polarization, have severely limited the widespread use of this technique. These problems are not insurmountable, and it is anticipated that more applications of this technique to interesting and important chemical problems shall be undertaken in the future.

Introduction

Clusters are defined as homogeneous aggregates of atoms (A_n) or molecules (M_n), although mixed (heterogeneous) aggregates (X_nY_m or X_nY^+) are also considered as clusters. The size range of interest starts at the dimer ($n=2$) and reaches up to 10^6 to 10^8 constituents per cluster. Depending on the nature of the building blocks, the binding energy between the constituents can be rather weak, as in the case of van der Waals bound rare gas clusters (10–100 meV), or rather large, as in the case of covalently bonded carbon clusters (several electron volts). Gas-phase clusters can be produced either by fragmentation of solid material (laser desorption or sputtering into vacuum) or by aggregation of single particles (supersonic jet expansions, gas aggregation); the clusters may be either neutral or ionized. Owing to the statistical nature of these methods, the cluster sample (beam) usually comprises a broad distribution of different cluster sizes (a notable exception being the formation of C_{60}). Thus, virtually all experiments – in particular those concerned with the properties of a single cluster size, or with the evolution of cluster properties as a function of size – rely on mass spectrometry as a major tool for investigating this unique form of matter.

Besides high mass resolution for the proper identification of a specific cluster ion (Figure 1), one of the most important requirements for cluster studies is a large mass range (see Figure 2 which shows a photoionization time-of-flight (TOF) mass spectrum of caesium oxide clusters). This has led to the sophisticated and improved use of established techniques and the innovative development of new concepts in mass spectrometry (electrospray ion sources, reflection type mass spectrometers, etc.), which nowadays are also of great use in other fields such as medicine and biology for the investigation of large biomolecules. Besides identification of cluster ions and cluster ion distributions, the other major use of mass spectrometry in cluster science is the selection of mass-analysed monodisperse cluster ions to allow the investigation of cluster ion properties such as the structure, energetics, stability and reactivity. While size-selected neutral cluster targets are usually unavailable, mass spectrometry plays a crucial role in their investigation as well. For example, the information gained from

photoelectron spectroscopy of mass-selected metal cluster anions pertains to the neutral species. Likewise, the sizes of neutral clusters that are interrogated by charge transfer reactions or resonance-enhanced ionization can be determined in a mass spectrometer, provided fragmentation does not occur.

Atomic Structure

The geometric arrangement of atoms is of paramount interest in cluster science. Mass spectrometry has provided essential clues to cluster structure and morphology, even though the approach is indirect. In short, one attempts to relate anomalies in the size distribution of clusters to anomalies in their properties, such as stability, reactivity or ionization energy.

Figure 3 shows a mass spectrum of krypton clusters. Neutral clusters are grown by expansion of the gas through a nozzle into vacuum. Several abundance anomalies, often called ‘magic numbers’, are observed. Two questions arise: (1) Assuming the numbers indicate enhanced stability, is there a growth sequence that can consistently explain them? (2) Do the anomalies exist before ionization, or are they caused by dissociation following ionization?

Figure 1 Section of a high resolution C_{60} mass spectrum obtained by multistep electron impact ionization. The black peaks are calculated isotopomers of the septuply charged C_{60}^{7+} ion normalized to the first isotopomer of the experimental run. Figure 3 Mass spectrum of krypton clusters, grown in a supersonic expansion and ionized by electron impact. The cluster size and assumed cluster structure of particularly prominent mass peaks are indicated.

Atoms in rare gas solids arrange in a close-packed structure, each atom being surrounded by 12 nearest neighbours. Clusters of rare gases are expected to assume compact shapes. Hence, it is reasonable to assume that clusters grow layer by layer around a core comprising 13 atoms, and that closed shells are particularly stable. The abundance of these clusters will be enhanced if clusters are warm enough to evaporate atoms.

Figure 4 Schematic view of a 13-atom icosahedron and a 13-atom cuboctahedron.

However, the 13-atom core may be either a cuboctahedron cut out of the fcc crystalline solid, or an icosahedron (**Figure 4**). Either way, the total number of atoms in complete-shell clusters would be 13, 55, 147, 309, 561; these cluster sizes are, indeed, particularly abundant in the mass spectra. **Figure 3** reveals several additional magic numbers. They indicate closure of subshells that occurs whenever a facet of the cluster is covered by a layer of atoms. A cuboctahedral cluster has 14 facets and the icosahedral one has 20, leading to distinct subshell closures. For argon through xenon in this size range, only the icosahedral growth sequence can explain the observed anomalies.

Theory and a large number of experiments concerning ionization, indicate that it is essentially impossible to 'softly' ionize a rare gas cluster or, in fact, any cluster with van der Waals bonding. Dissociation will lead to enhanced intensities for particularly stable charged clusters; metastable decay will cause the relative intensities to become time dependent (**Figure 5**).

Likewise, mass spectra of small clusters formed in the charged state, for example by sputtering, may deviate considerably from spectra of clusters formed in the neutral state. For larger clusters, however, neither the system (Ar, Kr, Xe) nor the cluster formation/ionization process affects the anomalies.

Magic numbers in spectra of calcium and strontium clusters also indicate icosahedral growth, while aluminium clusters appear to adopt an fcc structure with octahedral morphology. Magic numbers observed when metal atoms are grown around a cluster of known geometry, C_{60} , nicely confirm the power of the closed-shell or closed-subshell concept.

Mass spectra of transition metal clusters do not exhibit any abundance anomalies. However, if they are mixed with reactive gases prior to expansion into vacuum, the number of molecules being absorbed exhibits pronounced size effects. Mass spectra may directly reveal the number of reactive sites on the cluster surface; Co_{19} , for example, offers six highly reactive sites towards ammonia. This number tends to increase with cluster size,

but local minima are observed at certain cluster sizes, indicating closed shells or subshells in agreement with an icosahedral growth sequence.

The stoichiometry of NaCl cluster cations is $(NaCl)_nNa^+$. A pronounced sequence of magic numbers is observed if $n=13, 22, 37, 62, 87$ etc. Assuming the ionic arrangement in the cluster is that of a crystal (rock salt, fcc lattice), compact shapes can be obtained by cutting cuboids out of the crystal. The number of ions in such a cuboid is odd only if the number of ions along each edge is odd. The numbers n listed in the preceding text correspond to cuboids with $3 \times 3 \times 3$, $3 \times 3 \times 5$, $3 \times 5 \times 5$, $5 \times 5 \times 5$ and $5 \times 5 \times 7$ ions. Several other alkali halide clusters show the same pattern.

A magic number in mass spectra of carbon clusters has ultimately led to the discovery of a new form of crystalline carbon. **Figure 6** displays spectra of carbon clusters formed by laser vaporization into helium gas with subsequent expansion into vacuum. Only even-sized clusters are observed above $n=30$. Smaller clusters, which are known to form chains and rings, occur for odd and even sizes. A structural transition takes place near $n=30$. Ion chromatography has revealed that various structural isomers may co-exist. The abundance anomalies at $n=60$ and 70 become more pronounced if the helium gas density is raised (**Figure 6**, upper spectrum). The structure of carbon clusters in this size range can be

Figure 5 Section of a Ne_n^+ cluster ion mass spectrum in the vicinity of the magic number size $n=55$ measured approximately $68 \mu s$ (upper trace) and $118 \mu s$ (lower trace) after the primary ionization event. After Märk TD and Scheier P (1987) *Chemical Physics Letters* 137: 245.

Figure 6 Mass spectrum of carbon clusters formed by laser vaporization into helium gas of high pressure (upper spectrum) and low pressure (lower spectrum). Reproduced from Kroto HW, Heath JR, O'Brien SC, Curl RF and Smalley RE (1985) *Nature* 318: 162 with permission of Macmillan Magazines Ltd.

described as that of a graphitic sheet which is curved and closed upon itself by replacing 12 hexagons with pentagons. C_{60} is the smallest of these so-called fullerenes in which all pentagons can be separated by hexagons; it has icosahedral symmetry. C_{70} would be the next larger fullerene with no adjacent pentagons. The unusually large enhancements of C_{60} and C_{70} in **Figure 6** reflect their inertness towards growth. Later research has led to the synthesis of macroscopic amounts of C_{60} and larger fullerenes. They are stable in air and, unlike other clusters, do not react with each other.

Fullerenes are hollow; C_{60} can cage atoms as large as xenon. The 'endohedral' nature of a complex may be demonstrated by its stability. $(\text{HeC}_{60})^+$, formed by collisions of C_{60}^+ with helium gas, survives neutralization and re-ionization. The number of carbon atoms required to cage an atom depends on the size of the latter: photo-excited $(C_nK)^+$ will lose C_2 units until, below $n=44$, potassium escapes. $(C_nCs)^+$, however, requires at least 48 carbon atoms.

Abundance anomalies as discussed earlier relate to unique atomic structures. Molten clusters will not exhibit magic numbers. This has been utilized to determine melting temperatures of clusters in the gas phase. If sodium clusters are thermalized in warm helium and then allowed to effuse into vacuum, no magic numbers related to atomic structure are observed. If the gas is cooled to 307 K (83% of the bulk melting temperature), magic numbers appear for clusters of size $n \geq 6000$. They extend to smaller clusters if the temperature is lowered further. Smaller clusters melt at lower temperatures. Molten sodium clusters show a different sequence of magic numbers as explained in the following section.

Electronic Structure

Key features of the electronic structure of some non-transition metal clusters were first revealed through mass spectrometry. **Figure 7** shows a mass spectrum of sodium clusters, grown from vapour in cold helium gas and ionized by light from a UV lamp. Abundance anomalies are observed at $n=8, 20, 40$ and 58 . If, instead, alkali clusters are ionized by an intense pulsed laser in the visible or near UV, abundance anomalies are observed at $n=9, 21, 41$ and 59 . It appears that cluster stability is enhanced whenever the number of valence electrons, n_v , is 8, 20, 40, 58 etc. The mass spectrum in **Figure 7** is believed to reflect the abundance and, indirectly, the stability distribution of neutral clusters. However, multiphoton excitation leads to excessive dissociation of charged cluster ions, thus revealing the stability of cluster cations. Copper and silver clusters directly formed in the charged state by sputtering do indeed show the same magic numbers 9, 21, 41, etc. Experiments involving

other mono-, di- and trivalent metals provide further support for this hypothesis. For example, Cu_{13}^- and Ag_{43}^{3+} and Al_{13}^- (also see **Figure 8**) form local abundance maxima in their respective distributions.

Figure 7 Mass spectrum of sodium clusters, 'softly' ionized by low-intensity light from a UV lamp. After Knight WD, Clemenger K, deHeer WA, Saunders WA, Chou MY, and Cohen ML (1984) *Physical Review Letters* 52: 2141.

Figure 8 Mass spectrum of aluminium cluster anions before (upper) and after (lower) reaction with oxygen. Al_{13}^- is least reactive. After Leuchtner RE, Harms AC and Castleman AW Jr (1989) *Journal of Chemical Physics* 91: 2753.

The observed ‘magic numbers’ find an explanation in the ‘jellium model’, which assumes that the valence electrons move freely throughout the cluster, only confined by an effective potential that is approximately constant throughout the cluster, thanks to the shielding by the other free electrons. This quasi-free electron approximation may seem naive, but it successfully explains basic properties of many metallic solids. Making the approximation that the effective potential is spherically symmetric, one immediately predicts electronic shell structure: spherical symmetry gives rise to a degeneracy of the single-electron quantum states, the energy does not depend on the magnetic quantum number. Whenever a ‘shell’ of electrons is filled, addition of a monovalent atom implies that its valence electron has to occupy a higher state, making this extra atom less tightly bound. The energetic order of the first few shell closures is consistently predicted to occur at $n_e = 2$ (1s state), 8 (1p, in the notation used in nuclear physics), 18 (1d), 20 (2s), 34 (1f), 40 (2p), 58 (1g), etc. for the simple square-well potential as well as for more sophisticated potentials calculated self-consistently. Some of these gaps, like that between the 1d and 2s states, may be quite small, explaining the absence of an abundance anomaly at $n_e = 18$.

Many related effects have been studied in detail. Dissociation energies have been derived from metastable decay rates of alkali cluster ions. The gaps between electronic shells have been probed by measuring the size dependence of the ionization energy. Reduced ionization energies are, indeed, found for systems with 9, 21, 41, etc. valence electrons. The anomalies are much less than predicted, but refined effective (spherically non-symmetric) potentials can explain this trend as well as the observation of some additional fine structure in the size distribution and in the ionization energy. Additional information has been obtained from photoelectron spectroscopy of neutral and negatively charged clusters. Again, the basic features of these spectra and their size dependence can be rationalized within the jellium model.

Classically, the ionization energy $E_{\text{ion}}(R)$ of a metallic sphere of radius R is expected to converge to the bulk value W (the work function) as $E_{\text{ion}}(R) = W + \text{const } R^{-1}$ (for a compact cluster of size n , the radius will scale as $n^{1/3}$). This behaviour is indeed observed for most metal clusters, except for the local anomalies mentioned earlier. Mercury, however, behaves differently (Figure 9). For small sizes, the ionization energies are significantly larger than expected, but a transition to the expected asymptotic behaviour occurs between $n \cong 20$ and 70 ($R \cong 5\text{--}8 \text{ \AA}$). This phenomenon has been assigned to a transition from an insulator to a metallic system.

The jellium model also provided a motivation to develop high-resolution mass spectrometry of very large clusters. Although the gaps between electronic states will gradually disappear with increasing level density, that is

Figure 9 Ionization energy of mercury clusters (solid circles, crosses) versus (estimated) reciprocal cluster radius. The slow convergence to the behaviour expected classically for a metallic sphere (dashed line) is attributed to the occurrence of an insulator-to-metal transition in the size range between 20 and 70 atoms. After Rademann K, Kaiser B, Even U, and Hensel F (1987) *Physical Review Letters* 59: 2319.

with increasing cluster size, they were predicted to decrease in a non-monotonic fashion owing to interference effects between different types of semiclassical orbits of the quasi-free electrons in the clusters. These ‘super-shells’, originally predicted for nucleonic systems much larger than naturally occurring nuclei, have been confirmed for clusters of sodium, lithium and gallium containing thousands of valence electrons.

Cluster Ion Reactivity

Two categories of reactions have been studied that require the temporal evolution of the cluster ion composition to be known. The first comprises reactions of (neutral or ionized) clusters with neutral or ionized atoms, molecules, clusters or surfaces (not to mention reactions of photons or electrons with the clusters which, however, are usually discussed in the context of ionization and dissociation reactions); the second deals with reactions inside (excited) cluster ions. In the first case, the mass spectrometer in various combinations serves as the chemical reactor, whereas in the second, the cluster itself may be considered to be the chemical laboratory.

Cluster Ion Reactions

One of the interesting questions addressed in this field is the influence that solvation, the degree of aggregation and the proximity of solute complexes have on the reactions and properties of reactive species. Huge changes (by many orders of magnitude) of the corresponding reaction rate constants may occur when going from the gas phase to the cluster environment; or very specific

selectivity may be observed in reaction channels for metal cluster ions reacting with ligands (see **Figure 8**). Moreover, research on the reactivity of naked metal cluster ions is of special interest as these systems are considered to be potential catalysts since, in general, they are highly unsaturated. Fe_4^+ ions, produced by sputtering, thermalized and trapped in the storage cell of a FT-ICR mass spectrometer, were shown to react sequentially with ethylene, forming benzene precursors. The existence of these precursors and the occurrence of a complete catalytic cycle has been shown in an MS^5 experiment, where the various intermediates are successively identified.

Reactions between clusters may lead to fusion-like reactions, such as $\text{C}_{60}^+ + \text{C}_{60} \rightarrow \text{C}_{120}^+$, where fusion occurs only for collision energies exceeding a barrier of approximately 70 eV. However, they may cause fragmentation and even multifragmentation reactions, the latter showing an activation energy of approximately 70 eV for C_{60} . Studies involving various types of tandem mass spectrometer combinations have, in addition, dealt with the rapidly growing topic of cluster ion/surface reactions. Besides reflection, surface-induced dissociation, charge exchange and surface-induced reactions have been observed, thus allowing study of the reactivity and, in addition, the structure of these ions. For instance, collisions of size-selected stoichiometric and non-stoichiometric acetone ions with a stainless steel surface covered by hydrocarbon always give, besides typical fragmentation patterns expected for weakly interacting van der Waals cluster ions, the protonated acetone ion as the major secondary ion. Using deuterated acetone it is possible to distinguish two completely different reaction routes leading to this major product ion, one involving an H abstraction (pick-up) reaction with the surface adsorbates and one involving an ion molecule reaction within the cluster ion (intracluster reactions). The branching ratio for these two reactions depends strongly on the cluster size. Again, the ultimate goal is to study new reactions in the novel nonequilibrium environment present under the ‘nano-shock’ conditions shortly after cluster impact on the surface.

Reactions in Cluster Ions

One of the most fascinating aspects of cluster reactivity is given by those unimolecular reactions that occur inside of an energized cluster (ion) after excitation/ionization by, for example, electrons or photons. Whereas inelastic interactions of free electrons with gas-phase atoms or molecules result in changes of the electronic configuration or nuclear motion, interactions of electrons with clusters may, in addition, (1) comprise multiple collisions of the incoming (scattered) electron(s) and (2) involve subsequent intra- and intermolecular reactions within the

‘cluster reactor’. This sequence of events leads to the formation of excited cluster ions (which may differ in composition and stoichiometry from the initial neutral precursor), involving the deposition of excess energy into various degrees of freedom. Energy and charge exchange between different sites in the cluster may, in turn, cause additional spontaneous reactions not present in ordinary gas-phase molecules. These spontaneous reactions, occurring on time scales ranging from a few vibrational oscillations up to the millisecond time regime, will contribute strongly to the final fragmentation pattern observed in mass spectrometry. They are also responsible for the fact that measured cluster mass spectral distributions are often quite different from the distribution of clusters in the probed neutral beam and are usually only snapshots of the changing ion compositions after a primary ionization or excitation event (see **Figure 5**). Here, from the large number of different types of reactions, only four examples will be discussed, namely two internal ion molecule reactions and two unimolecular cluster decay reactions.

Reactions in the cluster may lead to the production of ions not produced in the case of the monomer, and vice versa. For instance, electron impact ionization of CO_2 does not give O_2^+ fragment ions, whereas electron impact ionization of CO_2 clusters yields $(\text{CO}_2)_m\text{O}_2^+$ ions by the following reaction sequence via dissociative ionization of a single CO_2 molecule within the cluster; the incoming electron produces an O^+ fragment ion. In a second step, this fragment ion, via an ion molecule reaction with a neighbouring CO_2 molecule, forms O_2^+ plus CO.

In contrast, for polyatomic molecules, fragment ion abundances are usually much smaller if the ionization and subsequent fragmentation occur within a cluster. For instance, for a propane cluster, the relative abundance of the parent molecular ion C_3H_8^+ and the abundances of the first-generation fragment ions C_3H_7^+ , C_3H_6^+ , C_2H_5^+ , C_2H_4^+ are significantly enhanced; those of the second-generation fragment ions C_3H_5^+ , C_3H_4^+ , C_2H_3^+ , C_2H_2^+ are diminished in comparison to the situation with the monomer. This is due to energy transfer from the originally excited propane molecular ion, via quenching reactions, to the cluster constituents.

The common unimolecular (spontaneous) decay in the metastable time regime for (excited) cluster ions is monomer evaporation, although in certain cases dimer and trimer ejection have also been observed. Whereas electronic predissociation and barrier penetration are likely mechanisms for the decay of small cluster ions, vibrational predissociation is the dominant metastable dissociation mechanism for larger cluster ions, leading in some cases — owing to the large amount of energy stored — to sequential decay series. Moreover, because cluster ions of a specific size produced in the ion source of a mass spectrometer by electron impact of a neutral

cluster beam will comprise a broad range of internal energies (owing to the statistical nature of the complicated ionization process and the possibility of cascading from different neutral precursors), the decay of such an ion ensemble will not be governed by a single decay constant k as predicted by RRKM theory for a polyatomic ion excited to a specific energy. The experimental results show, in accordance with predictions using the concept of an evaporative ensemble model (EEM), a non-exponential function for the time dependence of the apparent metastable decay rate (Figure 10). Moreover, this EEM model can be also used to describe the experimentally observed increase of the apparent decay rate with cluster size. Deviations observed from the prediction are due to the special nature of 'magic number' cluster sizes. It is thus not surprising that these anomalously small or large decay rates agree in a mirror-like fashion with enhanced or depleted ion abundances in the mass spectrum.

In addition to the single monomer evaporation based on the statistical predissociation mechanism, several unusual metastable fragmentation reactions involving the ejection of more than one monomer have been observed. It has been demonstrated by mass spectrometric techniques that these decay reactions are due to the decay of isolated excited states within the cluster ion, including vibrational states, excimers and isomers.

Hot surfaces may 'boil off' electrons if the corresponding activation energy is not much higher than that for the competing reaction, evaporation of atoms. For energetic reasons, this 'thermionic emission' process is not observed for ordinary molecules unless they are negatively charged (autodetachment). The cohesive energy per building block tends to increase with increasing

cluster size, while the ionization energy decreases. Also, a large system can store excitation energy more effectively than a small molecule; the cluster can serve as its own heat bath. Hence, delayed electron emission from neutral clusters excited by photons or by collisions is a viable reaction. This process produces asymmetric peaks in conventional TOF mass spectra, because the arrival time of an ion is usually measured with respect to the time at which the parent molecule was excited. Figure 11 (top) shows a TOF mass spectrum of a C_{60}/C_{70} mixture, using multiphoton excitation at 266 nm. To select the time of ionization separately from the TOF through the instrument, the extraction field is modulated in time such that only ions formed within a certain time interval (4–5 μ s in this case) reach the detector, thus giving rise to narrow mass peaks that reflect the rate of formation within the chosen time interval (Figure 11, lower). It becomes apparent that C_{58}^+ and other fragment ions also have delayed components. C_{60}^+ may form hundreds of microseconds after excitation. Delayed ionization has been observed for neutral refractory metal clusters containing as few as five atoms, for some metal oxides and for metallocarbohedrenes such as Ti_8C_{12} . The phenomenon is ubiquitous for negatively charged clusters owing to their reduced activation energy for electron emission.

Figure 10 Measured and predicted (solid line) apparent metastable decay rates (metastable fraction divided by the experimental time window) for three different cluster ion sizes and two different rare gases (open symbols, argon; filled symbols, krypton) versus time since electron ionization. After Ji Y, Foltin M, Liao CH, and Märk TD (1992) *Journal of Chemical Physics* 96: 3624.

Figure 11 Time-of-flight mass spectrum of multiphoton-ionized fullerenes. Upper spectrum: static extraction, delayed ions give rise to asymmetric peaks. Lower spectrum: pulsed extraction, delayed ions formed within a chosen time window are bunched into narrow peaks.

Multiply Charged Clusters

Systems with a high charge density become unstable with respect to dissociation into charged fragments (fission). This effect limits the net charge of molecules, small clusters, and droplets of a given size, as well as the size of natural and man-made atomic nuclei. Multiply charged cluster ions are easily identified by their non-integer size-to-charge ratios (**Figures 1 and 12**). However, for each charge state z there is a characteristic appearance size n_z below which the species becomes undetectable, as shown in **Figure 12** for argon. For more tightly bound metal clusters, $n_{z=2}$ may be as small as 2, but the concept of an appearance size is still meaningful for higher charge states.

The effect has been observed for various atomic and molecular van der Waals clusters, hydrogen-bonded clusters and metal clusters. Sevenfold sodium clusters, for example, are not observed below $n_7 \cong 445$. Under typical experimental conditions, multiply charged clusters are, like their singly charged counterparts, thermally excited; they are found to evaporate atoms or molecules in a statistical, unimolecular process if their size is well above the appearance size. In the vicinity of the latter,

Figure 12 Mass spectrum of argon clusters ionized by electron impact. Doubly and triply charged clusters are observed above characteristic appearance sizes.

however, fission competes with evaporation. Below the appearance size, the rate of fission greatly exceeds the time needed for mass spectrometric detection. The appearance size can be somewhat reduced if colder multiply charged clusters are generated. Ultimately, however, the clusters become unstable and the fission barrier vanishes.

The size distribution of fission fragments can be determined mass spectrometrically. Distributions tend to be asymmetric, but there are considerable variations in the details. Several studies have been devoted to fullerenes. C_{60}^{z+} is observed with charge states up to $z=9$. Spontaneous (unimolecular) dissociation of C_{60}^{3+} , as well as producing C_{58}^{3+} and smaller fragments, produces C_{54}^{2+} , C_{56}^{2+} and C_{58}^{2+} via a 'charge separation' reaction (**Figure 13**). These MIKE spectra (scan of the electric sector field voltage) reveal the energy released upon fissioning. C_{54}^{2+} shows the greatest broadening because it is related to the heaviest fission partner, C_6^+ . Detection of the light fission fragments is difficult because of their large recoil velocity, but C_6^+ has been directly identified.

Cluster Anions

Often a single molecule cannot bind an excess electron, although it is quite possible to trap electrons in liquids and solids of these molecules. Negatively charged clusters of these substances are of particular interest since it is possible to study details of this trapping as a function of aggregation. It has been shown by mass spectrometry that three mechanisms are responsible for the occurrence of negatively charged stoichiometric cluster anions in these cases: (1) stabilization by collision if accommodation of

Figure 13 MIKE scan of C_{60}^{3+} in a double focusing sector field mass spectrometer, showing in addition to the parent ion spontaneous fission into different fragment ions. The broadening and splitting for the charge separation reactions arises from the large kinetic energy release in these reactions. Reproduced from Scheier P, Dünser B, Wörgötter R, et. al. (1996) *International Review of Physical Chemistry* 15: 93 with permission from Taylor & Francis.

Figure 14 Mass spectrum of negatively charged $(\text{NH}_3)_n^-$ clusters showing a sharp onset around the minimum appearance size $n_{\min} = 35$. After Haberland H, Schindler HG, and Worsnop PR (1984) *Berichte der Bunsengesellschaft für Physikalische Chemie* 88: 270.

the electron affinity leads to autodetachment for a single isolated molecule (e.g. O_2); (2) stabilization by solvation if Franck–Condon problems lead to dissociation (e.g. CO_2); and (3) generation of a solvated electron (polaron) if the electron affinity of the monomer is zero (e.g. H_2O). Whereas in the first two cases attachment of an electron to the cluster leads to the production of monomer anions and higher analogues, in the last case only cluster anions above a certain minimum size $n_{\min}$ can be observed (see **Figure 14** showing $n_{\min} = 35$ for ammonia clusters). It turns out that this minimum size in the observed mass spectrum may depend on the method of anion production. Cluster anions of volatile compounds can be formed in the gas phase either by injection of free electrons into the expansion zone of a supersonic jet or by attachment of electrons to a beam of pre-existing neutral clusters. For water clusters, one obtains $n_{\min} = 2$ in the former and $n_{\min} \cong 11$ in the latter mode. Calculations show that the electron is localized in a ‘surface state’ for the very small water cluster anions ($n = 2\text{--}8$); vertical detachment energies measured by photodetachment methods are, in fact, very low. Thus long-lived anions below $n \cong 11$ can only be produced in the special (cold) environment of the expanding jet.

In addition to the production of stoichiometric cluster anions, non-stoichiometric fragment cluster anions have also been observed (e.g. $(\text{O}_2)_m\text{O}^-$ for oxygen). Whereas these fragment anions can usually be produced by attaching electrons to pre-existing clusters at energies similar to the known resonances for the monomer (e.g. at around 6 eV and higher for (O^-/O_2)), the stoichiometric anions are, in addition, often produced with very high probability at energies close to zero. **Figure 15** shows the region of the ‘zero-energy’ resonance of oxygen clusters

Figure 15 Measured (full line) and calculated (broken line) O_2^+ anion signal produced by electron attachment to an oxygen cluster beam as a function of electron energy. Inset: Same data on a log–log scale demonstrating the E^{-1} dependence predicted by s-wave scattering theory (dashed line). as measured with a high-resolution spectrometer. In addition to the zero-energy peak ascribed to s-wave capture by the entire cluster, further peaks are observed; these are attributed to vertical attachment of the incident electron to a single molecule within the cluster, thus allowing probing of the vibrational levels of a single oxygen anion within the cluster.

Symbols

f_i	frequency
I_0	signal intensity without NOE
I_{eq}	signal enhancement
J	coupling constant
k_0	base chemical shift
n	number of neighbouring carbon atoms
S	signal
t	time
T_1	spin–lattice relaxation time
T_R	repolarization time
α_E	Ernst angle
γ	magnetogyric ratio
δ	chemical shift

The analysis of carbonaceous materials with spectroscopy takes on special importance because, without doubt, the study of the chemistry of carbon is more extensive than that of any other element. The strong sensitivity of NMR parameters to chemical state has long made NMR spectroscopy a favourite tool for analysis of organic materials. Early on, proton NMR spectroscopy was used to analyse materials, but with the development of ever more sensitive instrumentation, the NMR analysis of carbon in organic molecules has become the essential tool for identification of carbon-containing materials.

Several isotopes of carbon occur naturally. The most abundant isotope of naturally occurring carbon is ¹²C, which comprises 98.90% of all carbon. It has no magnetic moment and therefore is not active in NMR spectroscopy. Most people are familiar with the existence of ¹⁴C, a minute percentage of naturally occurring carbon, because, through measurement of its radioactive emissions, one can define the age of certain ancient objects. It is not NMR active because its spin is also zero. ¹³C, comprising only 1.10% of naturally occurring carbon, is the carbon isotope on which NMR spectroscopists focus strongly because it has a spin of 1/2 like the proton or the ¹⁹F nucleus.

Properties of the ¹³C Nucleus

The NMR properties of ¹³C (Table 1) give an indication of both the strengths and the weaknesses of analysis using

Table 1 ¹³C NMR properties

Abundance	0.011
Spin	1/2
Gyromagnetic ratio (Hz T ⁻¹)	1.0705×10^7
Typical shift range (ppm)	220
Receptivity relative to ¹ H	1.59×10^{-2}

it. The gyromagnetic ratio of ¹³C is approximately one-fourth that of the proton and, as a result, the resonance condition for ¹³C at a given magnetic field strength occurs at a radiofrequency approximately one-fourth that of the proton resonance. For a sample with equal numbers of spins and equal spin–lattice relaxation rates, the predicted signal-to-noise ratio of the ¹³C spectrum at a particular magnetic field strength would be over an order of magnitude lower than that of a proton spectrum. Additionally accounting for the concentration difference due to the natural abundance, one finds that typically the absolute receptivity of ¹³C relative to the proton is only 1.76×10^{-4} . Thus, there are difficulties with obtaining ¹³C NMR spectra compared to ¹H NMR spectra. However, the utility of carbon NMR in studies of organic molecules guarantees that ¹³C will be one of the nuclei more heavily investigated by NMR spectroscopists.

Single-Pulse Fourier Transform NMR

The analysis of carbonaceous materials would indeed be difficult if it were not for the fact that Fourier transform NMR spectroscopy allows one to increase the signal-to-noise ratio by co-adding experiments. The simplest experiment is the gathering of the response to a single pulse. The length of the pulse for maximum signal, the $\pi/2$ pulse, on most modern spectrometers is typically in the range of 5 to 10 μ s. Data acquisition goes on for a time that depends on the spectrum width and resolution desired, often for times greater than a second.

In the single-pulse experiment, an important parameter is the rate at which the experiment can be repeated, determined by the time it takes to repolarize the system after the magnetization has been destroyed in the excitation and acquisition. This is a function of the spin–lattice relaxation time, T_1 , of the carbons in the sample. For typical small organic molecules, T_1 can be of the order 10 to 60 s or more at room temperature. A rule of

thumb for quantitative evaluation of NMR spectra is that the repolarization time is five times the longest T_1 in the sample. For some samples, particularly those containing quaternary carbon atoms or carbonyl groups, this time can be substantially longer than a few minutes. Thus, a compromise is often struck, in which the repolarization time is shortened to some few tens of seconds, with the knowledge that certain resonances may be attenuated, making the resultant spectrum non-quantitative.

Another compromise involved to obtain data faster is to use a pulse width different from $\pi/2$ and a repolarization time shorter than $5T_1$. For a resonance with a relaxation time, T_1 , and a repolarization time, T_R , one may calculate the angle, α_E (the Ernst angle), that gives the largest signal-to-noise by coaddition in a given time:

$$\cos \alpha_E = \exp\left(\frac{-T_R}{T_1}\right) \quad [1]$$

The variation of the Ernst angle with T_R/T_1 is shown in **Figure 1**. The optimal pulse angle may be substantially less than $\pi/2$ for typical conditions encountered for carbon NMR spectroscopy where the repolarization time is short compared to T_1 . For a fixed repetition time, the Ernst angles of carbons in a sample will not be identical because T_1 varies from carbon to carbon. Thus, even in defining the pulse angle, some compromise must be made, depending on the range of T_1 values in the sample.

Figure 1 The Ernst angle as a function of the ratio of the repolarization time to the spin-lattice relaxation time.

Heteronuclear Decoupling

Detection of the ¹³C NMR spectrum of an organic compound in solution with the single pulse experiment, as described above, is quite feasible. However, were the spectrum acquired in this manner, one would notice that the number of peaks in it exceeds the number of unique carbon environments. Most organics contain protons as well as carbon atoms. These protons are coupled to the carbons through the indirect (or scalar) J coupling, resulting in splitting of the carbon resonances of any carbon with attached protons.

Generally, carbons are coupled to one (AX), two (AX₂) or three (AX₃) protons. In these cases, one sees the appearance of a doublet (AX), a triplet (AX₂) or a quartet (AX₃). If the carbon is coupled to several chemically distinct protons, one may see patterns that arise from spin systems labelled AXY, AX₂Y, etc. These splittings contain information on the coupling constants between carbons and protons that can be of value in structure elucidation, but frequently the study of carbon NMR spectra focusses mainly on the unique carbon environments in a sample, and the splitting that the coupling brings only confuses the analysis. Thus, carbon NMR spectra are often obtained with simultaneous irradiation of the offending protons which suppresses the effects of coupling – the heteronuclear decoupled NMR experiment.

One question sometimes asked is why it is not necessary also to decouple the carbons from one another. Because of the low natural abundance of ¹³C, it is not very likely that a ¹³C will be near another spin-active ¹³C. Coupling requires relatively close proximity of the spins that are coupled, and it is simply quite unlikely that the spectrum has contributions from molecules containing two or more ¹³C atoms in a sample with the natural abundance of ¹³C. For sample containing substantial enrichment of the carbon in ¹³C (e.g. to increase signal in a single scan), such couplings may affect the spectrum and consideration of them is an important point to keep in mind.

Another important feature of carbon spectroscopy is the fact that the spectrum in natural abundance is really a superposition of spectra from different molecules, each with substitution of ¹³C at different sites in the molecule. The spectrum is not that of a single molecule with ¹³C at each position. This fact is sometimes forgotten because the analysis of the spectrum is often presented as if one were analysing a single molecule.

Heteronuclear decoupling is effected by irradiation of the protons during the acquisition of the carbon signal. While this may sound simple, the process can be quite complex. For example, exposing the protons to a single-frequency excitation will only decouple protons whose resonances are at that frequency; others will be more or less affected, depending on how close their resonances

are to the irradiation frequency. Thus, NMR spectroscopists have developed ways to irradiate over a band of frequencies that encompasses all of the protons coupled to the carbons. One means to spread the irradiation over the various protons is noise modulation of the proton excitation. This random modulation can be shown to result in excitation in a band that will excite all of the protons coupled to carbons. Such a technique is known as 'noise decoupling' or 'broadband decoupling'.

The use of decoupling with pure-frequency sources has been important in assigning resonances, since the observation of collapse of a coupling pattern indicates the existence of coupling between the carbon and the particular proton resonance irradiated. Experiments providing similar information are 'off-resonance decoupling' and 'spin ticklings'. In these cases, the centre frequency of the noise irradiation or the field strength is varied to observe the effects on the resonance lines of coupling partners. From these, one gathers information on the coupling partners, the sizes of couplings and the resonance frequencies of the coupling partners. In former times, such experiments were frequently the method of choice to assign resonances; however, the current use of two-dimensional NMR methods (see later) to determine coupling partners probably presages the decline of the use of selective-decoupling techniques in the future.

Truly random noise decoupling deposits energy in the sample over a range of frequencies near the centre irradiation frequency. Unfortunately, most of this energy falls at frequencies where there are no proton resonances. This portion of the energy does no useful work in suppressing the coupling of protons to carbons, but it does affect the sample. The energy deposited ultimately results in heating of the sample. To limit heating and to extend the range of useful decoupling, in the early 1980s,

spectroscopists focussed on the possibility of using coherent pulse sequences to produce the same effect as noise decoupling – the suppression of effects due to coupling of carbons to protons. The techniques go by various acronyms such as MLEV-16 and WALTZ-16, and the concept behind them is quite simple. Coherent fast switching of a proton spin between its two spin states produces a kind of short-term cancellation of evolution due to the J coupling, as observed by the detected carbon magnetization. Importantly, because of the coherent nature of the process, the energy deposited in the sample goes to spin inversion, which limits heating of the sample. Most modern spectrometers implement some version of this technique when the spectrometer is performing an experiment with broadband decoupling.

The importance of heteronuclear decoupling can be seen in **Figure 2**, where the carbon spectra of ethanol obtained with and without decoupling are shown. The decoupled spectrum in **Figure 2b** shows only lines for the various unique carbons sites. The simplicity of the spectrum in **Figure 2b** indicates the power of decoupling in unravelling the spectrum of a complex material.

Nuclear Overhauser Enhancement

In the heteronuclear decoupling experiment, it has proved convenient to have noise decoupling active not just during acquisition, but also during the repolarization time between experiments. If the experiment is performed in this manner, the spectrum is modified by another effect, the nuclear Overhauser effect (NOE) enhancement. The presence of the perturbing field during the repolarization period affects the return to equilibrium of the spin system by saturating the proton resonance. This saturation directly impacts the cross-relaxation between the carbons

Figure 2 (a) Ethanol: the coupled ¹³C NMR spectrum; (b) the decoupled ¹³C NMR spectrum. The solvent resonance is indicated with an asterisk.

and protons, increasing the signal in the case of ¹³C. If the system is allowed to reach equilibrium under the perturbation during repolarization, one predicts an enhancement of the signal, I_{eq} , over the signal without the NOE, I_0 :

$$I_{\text{eq}} = I_0(1 + \eta) = I_0 \left(1 + \frac{\gamma_{\text{H}}}{2\gamma_{\text{C}}} \right) \quad [2]$$

This increase is about 2.998, making the detection of the carbon resonance easier. Of course, for a particular repolarization time, not all ¹³C spins in a sample may have reached an equilibrium. The NOE is maximal if the relaxation mechanism solely originates in the direct dipole–dipole coupling between protons and carbons. This mechanism seems to be dominant for carbons directly bonded to protons, but for quaternary carbons and carbonyl carbons, such is not the case, and reduced enhancements are observed for these carbons. For this reason, a spectrum obtained with the NOE present should not be considered quantitative.

The presence of the NOE can be avoided by turning proton irradiation off during the repolarization time between experiments. If the experiment includes the activation of the proton irradiation for decoupling during acquisition, one obtains a spectrum with no enhancement and with coupling suppressed. However, if the proton irradiation is off during acquisition and the repolarization time, the spectrum has no enhancement and displays all couplings. There are four possible kinds of experiment, depending on when proton irradiation is on, as indicated in Table 2. Spectroscopists often use the NOE in obtaining carbon spectra as it gives a significantly larger signal for many of the carbons in a sample.

Pulse Techniques for Analysis

The single-pulse NMR experiment is a powerful tool for analysing materials, especially carbon. However, there are questions and ambiguities that cannot be unravelled with this simple experiment alone. Some may be addressed with selective-decoupling techniques. However, the use

Table 2 Effects of decoupling and NOE in carbon spectra

Irradiation during repolarization time	Irradiation during acquisition	Character of the spectrum
No	No	Coupled, no enhancement
Yes	No	Coupled, with enhancement
No	Yes	Decoupled, no enhancement
Yes	Yes	Decoupled, with enhancement

of spectral-editing sequences, and ultimately 2D NMR, has aided assignment of resonances in carbon spectroscopy. As an example, knowing the number of protons to which a carbon is coupled brings additional information to the process of identifying the structure of some unknown carbon-containing material. Generally, the sequences for carrying out these investigations involve pulse excitation of the carbons and the protons in such a way that the magnetization from a particular carbon centre behaves in a predictable manner. The techniques are often referred to by spectroscopists in the acronymical shorthand so prevalent in many spectroscopies: DEPT, INEPT, APT, and many, many more. The techniques involve modulation of the spin evolution or outright transfer of polarization from one species to the other.

As an example, we discuss the so-called attached-proton test (APT). It involves the use of a spin echo, which is produced by a sequence of two pulses, as shown in Figure 3.

First, we discuss the simple spin echo produced by a single π pulse (Figure 3a). Consider a magnetic moment, subject only to the chemical-shift interaction, that lies initially along the x -axis of the rotating frame. After a time t , it will have moved ahead of the x -axis of the rotating frame by an angle determined by the time t and the chemical shift. The π pulse inverts this magnetic moment so that immediately after the pulse it sits at that angle behind the x -axis. During the subsequent period, however, it catches up to the x -axis, so that at a time t after the π pulse it is aligned with the x -axis as it was at the beginning. In effect, at that time, the position of the magnetic moment is as if it were not subject to a chemical shift.

Figure 3 (a) The single π pulse. (b) The gated-decoupling attached-proton test, showing the sequence applied to the carbons (top) and the sequence applied to the protons (bottom).

Second, consider a spin that has no chemical shift (i.e. it sits at the frequency of the excitation) but is subject to a J coupling to another spin. During the first period, the magnetic moment begins to deviate from the x -axis of the rotating frame, depending on its spin state and that of its coupling partner. Let us now apply a π pulse only to the spin under observation. Once again, the magnetic moment returns to alignment with the x -axis in the second period.

In a third experiment, we propose to carry out the experiment of **Figure 3b** on the spins. Once again, we assume that the chemical shift is zero, but the J coupling is not. During the first period, there is no evolution of the spin because the decoupling suppresses this interaction, so the magnetic moment remains along the x -axis in the rotating frame. The π pulse does not change the direction of the spin, since it is along the x direction. However, in the second period, the J coupling causes the magnetic moment to deviate from the x -axis, so that a time t after the π pulse, the magnetization is moved away from the x -axis by an amount determined by the time t and the J coupling.

Were we to carry out the same experiment with a non-zero chemical shift and a non-zero J coupling, we would discover that the evolution due to chemical shift would be cancelled but the evolution due to J coupling would not. Thus it is possible with this experiment to label magnetic moments at time t after the π pulse according to the effects of J coupling. If, at that point, an acquisition is started, the peaks in the resulting spectrum will have magnitudes corresponding to the amplitude at that time, which will be determined by the J coupling.

Consider an AX system subject to this experiment. The spectrum will show no splittings, for it is taken with decoupling. The amplitude of the line will oscillate with t . In particular, for $t = 1/J_{\text{CH}}$, this signal will appear totally inverted. However, a carbon not coupled to an X spin (such as carbonyl or quaternary carbon) experiences no deviation and gives a positive signal under the same set of circumstances. A careful examination of the evolution of the components of the AX₂ and AX₃ species shows that, under this same experiment, the signal of the carbon in an AX₂ environment experiences no net deviation of the magnetic moment at a time t after the pulse, whereas the AX₃ system experiences a net inversion. Thus, the response to such an experiment is a spectrum with the signals from AX and AX₃ inverted relative to those of A and AX₂. From such a spectrum, one can easily discriminate these kinds of environment, as one can see from the spectrum of **Figure 4**.

The utility of the APT sequence hinges on the fact that one may choose a time t that is equal to π/J_{CH} for all carbons in the sample. This will only be true if the coupling constant is similar for carbons in various environments. As it turns out, the coupling constants are frequently in the range of 120 to 150 Hz, which is a sufficiently narrow range to allow the technique to work

Figure 4 The APT spectrum of ethyl isobutyrate in deuteriochloroform. The solvent resonance is indicated with an asterisk.

Figure 5 The DEPT experiment. The top line is the sequence applied to the carbons and bottom is applied to the protons. The time t is fixed as $1/(2J_{\text{CH}})$.

relatively well. A typical value of t that is used in these experiments is 7 ms. However, it must be emphasized that there are systems for which the coupling constants are very different from this nominal range, and lines from these carbons will not necessarily appear to be of the 'right phase'; such deviations should always be checked by additional experiments with different values of t .

The other commonly seen spectral editing techniques used in carbon NMR involve the transfer of polarization from protons to carbons in particular ways. A good example of this type of experiment is the so-called DEPT (distortionless enhancement by polarization transfer) sequence (**Figure 5**). By careful choice of experimental parameters, one can obtain spectra that represent only the quaternary, only the methines, only the methylenes and only the methyl groups in the sample. This is done in this case by use of the sequence shown in **Figure 5**. Four spectra are obtained with $\delta = \pi/4$, $\pi/2$ and $3\pi/4$ in the sequence and a single-pulse experiment. **Figure 6** shows these spectra for ethyl isobutyrate. In **Figure 6a** all the lines appear. In **Figure 6b** all the lines except the quaternary carbons appear positive. In **Figure 6c** only resonances from CH groups appear. In **Figure 6d** the CH and CH₃ appear positive and the CH₂ groups appear negative. With these spectra, one can identify the various species present.

The INEPT (insensitive nuclei enhanced by polarization transfer) experiment is similar to the DEPT experiment, except that it uses an evolution period to produce the appropriate condition for spectral selection that depends critically on the size of the coupling constant. The technique is therefore somewhat more susceptible to artefacts resulting from the variability of coupling constants than is DEPT.

Two-Dimensional Carbon NMR Spectroscopy

Two-dimensional (2D) NMR spectroscopy is now used routinely for many analytical problems. A convenient way to conceptualize 2D NMR spectroscopic studies is

Figure 6 DEPT spectra of ethyl isobutyrate: (a) the single-pulse spectrum; (b) DEPT- $\pi/4$; (c) DEPT- $\pi/2$; (d) DEPT- $3\pi/4$. The triplet arises from the carbon of the solvent, deuteriochloroform.

to divide the time of a 2D pulse experiment into four periods:

Preparation → Evolution → Mixing → Detection

Characteristic time : t_1 t_2

During the preparation period the spin system is 'prepared' for the 2D experiment. This may entail a simple $\pi/2$ pulse or a complex series of pulses and delay times. These preparation pulses and delays are applied in such a way, depending on the experiment, as to produce a particular behaviour of the spins during the evolution period (time = t_1). The mixing period is needed in some 2D experiments to permit transfer of magnetization from one spin to another. The signal is finally detected in the detection period (time = t_2).

In a typical 2D experiment the evolution time t_1 is varied systematically. For every value of t_1 , the signal as a function of t_2 is collected in the detection period. The complete set of these signals (as a function of t_1 and t_2) constitutes the 2D data set, $S(t_1, t_2)$. Suitable Fourier transformation of $S(t_1, t_2)$ with respect to both t_1 and t_2 then produces the 2D spectrum, $S(f_1, f_2)$, where f_i denotes the frequency.

A large number of 2D experiments have been devised. A list of some simpler 2D experiments is shown in **Table 3**. These experiments can be broadly classified as either J -resolved or shift-correlated. In J -resolved experiments, the chemical shift δ and the coupling constant J are plotted to form a 2D representation with δ and J axes. In this way, the scalar coupling pattern for spins with different chemical shifts can be visualized clearly. In shift-correlated experiments, 2D plots with different chemical shifts can be obtained. These experiments are found to be very useful in resolving different spectral assignment problems.

Table 3 Some simple 2D experiments

Type	Name	Function
J -resolved	Homonuclear	Shows ^1H - ^1H coupling patterns; permits precise J_{HH} measurements
	Heteronuclear	Shows ^{13}C - ^1H coupling patterns; permits precise J_{CH} measurements
Shift-correlated	COSY (HH-COSY)	Permits correlation of ^1H signals through ^1H - ^1H couplings
	NOESY	Permits correlation of ^1H signals through NOE interactions
	HETCOR (CH-COSY)	Permits correlation of ^1H and ^{13}C signals through $^1J_{\text{CH}}$
	HMQC/HSQC	Gives similar information as HETCOR; indirectly detects the less receptive ^{13}C through the more receptive ^1H
	RELAY	Permits correlation of ^1H signals through relayed coherence; ^1H - ^1H or ^{13}C - ^1H
	CH COLOC	Permits correlation of ^{13}C - ^1H signals through long-range ^{13}C - ^1H coupling
	HMBC/HSQC	Gives similar information as COLOC; indirectly detects the less receptive ^{13}C through the more receptive ^1H
	2D INADEQUATE	Gives correlation of ^{13}C signals through direct ^{13}C - ^{13}C coupling

COSY = homonuclear chemical shift correlation spectroscopy; NOESY = 2D nuclear Overhauser effect (NOE) spectroscopy;

HMQC = heteronuclear multiple-quantum coherence; RELAY = relayed coherence transfer; COLOC = correlation via long-range coupling;

HSQC = heteronuclear single quantum coherence; HMBC = heteronuclear long-range coupling; INADEQUATE = incredible natural abundance double quantum transfer experiment.

An example is shown of the C–H HETCOR (heteronuclear shift correlations) experiment. The pulse sequence is given in **Figure 7**. In the preparation period, a $\pi/2$ pulse is applied to the ^1H nuclei (a), causing the ^1H magnetization to evolve with time t_1 . Midway in the evolution period, a π pulse is applied to the ^{13}C nuclei (b). The π pulse produces refocussing of the ^{13}C – ^1H coupling at the start of the mixing period (c). The mixing time Δ_1 is set to $1/(2J_{\text{CH}})$ to polarize the ^1H magnetization. At (d), $\pi/2$ pulses at ^1H and ^{13}C are simultaneously applied, prompting transfer of the ^1H polarization to ^{13}C , which is then detected with simultaneous ^1H decoupling to obtain the decoupled ^{13}C spectrum.

A C–H HETCOR plot for polypropylene is given in **Figure 8**. The projection along one axis gives the ^{13}C spectrum, and the projection along the other axis gives the ^1H spectrum. Thus, if the ^1H and the ^{13}C spectra are both partially assigned, this experiment sometimes permits the information to be combined in order to derive improved assignments of both spectra.

Originally, ^{13}C NMR chemical shifts had to be obtained from direct observation of ^{13}C resonances. Conventional NMR probes had the ^{13}C detector coil close to the sample for optimum filling factor and sensitivity, and a ^1H -tuned coil for heteronuclear decoupling further away. Inverse geometry probes have this

arrangement reversed to obtain best sensitivity for ^1H detection. The arrangement resulted from the development of 2D experiments that gives the ^{13}C chemical shifts indirectly via ^1H detection, using pulse sequence such as firstly HMQC (as listed in **Table 3**), and later HSQC both of which rely on the one-bond J_{CH} for correlation. The analogous HMBC pulse sequence uses two- or three-bond ^1H – ^{13}C couplings to allow correlation to quaternary carbons.

Spectral Assignments

Firstly, ^{13}C NMR spectroscopy is ideally suited for organic structure determination. As noted earlier, it is a rare spin (only 1.1% in natural abundance), which means ^{13}C – ^{13}C couplings are not usually seen. Secondly, the ^{13}C shift range is large (220 ppm), and neighbouring atoms (as far as ε position away) affect the chemical shift of a given carbon. Thirdly, the chemical shift is less sensitive than ^1H to inter- and intramolecular interactions, such as hydrogen bonding and self-association. As a result, in most cases a one-to-one correspondence can be made between an organic structure and the ^{13}C NMR spectrum.

The ^{13}C chemical shift is diagnostic of different functional groups. An abbreviated shift scale is shown in **Figure 9**. This shift scale is useful for spectral interpretation and is reminiscent of similar structure–spectral correlation charts used in infrared (IR) spectroscopy. Yet ^{13}C NMR provides much more detailed structural information than IR. It has been known since the 1960s that the ^{13}C shifts of alkanes are approximately additive with increasing number of substituents. Similar empirical additivity rules have been found for alkyl carbons with different functional groups and other additivity rules have been proposed for olefinic, aromatic and carbonyl carbons. These linear additivity rules are a distinct feature of ^{13}C NMR, and they simplify spectral interpretation.

There are literally thousands of papers using ^{13}C NMR for structure determination of organic materials.

^aSteric correction parameters (Table 5) apply to these substituents.^bNumber(s) in parentheses denote(s) the number of non-hydrogen substituents on the carbon in question.

To many NMR users, spectral assignment is an art that depends on experience and good memory. The shift scale in Figure 9, coupled with spectral intensities and other chemical information, often permits simple structures to be deciphered. For more complex molecules, one common method involves looking up in spectral libraries for either the compound in question or, if not available, compounds with similar structures. This process has been automated, and many computer-assisted structure-determination methods have been developed. Several research groups have been very active in advancing this important area.

Another commonly used method involves the empirical shift rules described earlier. For alkyl carbons, the

¹³C shifts can be approximated by a linear combination of additive terms related to the neighbouring functionalities

$$\delta_{\text{observed}} = k_0 + n_\alpha S_\alpha + n_\beta S_\beta + n_\gamma S_\gamma + n_\delta S_\delta + n_\epsilon S_\epsilon + S_c \quad [3]$$

where n_i refers to the number of i neighbouring carbons ($i = \alpha, \beta, \gamma, \delta$, and ϵ), S_i is a constant characteristic of the i th carbon and S_c represents steric corrective terms to be used for contiguous secondary, tertiary and quaternary carbons. One set of additive parameters is shown in Table 4. The term $n_\epsilon S_\epsilon$ is often neglected because it is usually insignificantly small. The steric correction parameters S_c are given in Table 5.

Table 5 Steric correction parameters, $S(i, j)^a$

i	$j = 1$	$j = 2$	$j = 3$	$j = 4$
Primary	0.0	0.0	−1.1	−3.4
Secondary	0.0	0.0	−2.5	−7.5
Tertiary	0.0	−3.7	−9.5	−15
Quaternary	−1.5	−8.4	−15	−25

^aDesignation i = the carbon in question, and j = number of non-hydrogen substituents directly attached to the α -substituent (applicable only to α -substituents marked with footnote a in **Table 4**).

A sample calculation for 2-ethyl-1-butanol is as follows:
 $(\text{CH}_3\text{CH}_2)_2\text{CH}-\text{CH}_2\text{OH}$

	C_1	C_2	C_3	C_4
Base	−2.3	−2.3	−2.3	−2.3
α	9.1	18.2	27.3	58.1
β	9.4	18.8	28.9	18.8
γ	−5.0	−8.5	0	−5.0
δ	+0.6	0	0	0
$S(2,3)$	0	−2.5	0	−2.5
$S(3,2)$	0	0	−11.1	0
Calculated	11.8	23.7	42.8	67.1
Observed	11.1	23.0	43.6	64.6

Computer programs have been written that automate the rather tedious arithmetic involved. One program provides predicted ¹³C shifts and spectra of organic compounds containing common functional groups by incorporating most of the reported activity rules.

In practice, spectral assignment of more complex structures or unknown compounds often requires a combination of assignment methodologies, with or without computer assistance and experimental techniques. Thus, for a given problem it is not unusual to obtain the single-pulse spectrum, the APT, INEPT and DEPT spectrum of a sample. If needed, 2D spectra are also obtained. The information gathered is used, together with shift-prediction or spectral-search methods, to determine the structure of the sample in question.

Summary

Carbon NMR is a valuable tool for the study of organic materials. The NMR parameters are directly correlated with the structural properties of the various carbon sites. Modern spectrometers make carbon spectroscopy on samples containing ¹³C feasible at natural abundance. With the development of modern NMR technology, a host of techniques may be applied to obtain a wide variety of information about the molecule under study. In particular, spectral-editing experiments can provide information on carbon–proton connectivity that aid in the

assignment of resonances and the elucidation of structure.

Introduction

High-resolution ¹³C NMR spectroscopy is in widespread and routine use in many laboratories as a tool for the identification of organic compounds. This article is intended to provide a compilation of the chemical shifts and coupling constants available from ¹³C NMR spectra and to show how these are related to molecular structures. ¹³C NMR of organic molecules in solution is particularly powerful because ¹³C chemical shifts, and spin–spin coupling involving ¹³C nuclei generally fall into well-defined ranges. Comprehensive tabulations of such values have been compiled (see Further Reading) and a number of computer-based predictive schemes have become available.

Chemical Shifts

Alkanes

¹³C NMR chemical shifts are referenced to that of tetramethylsilane (TMS) added as an internal standard and taken as 0.0 ppm. Often secondary standards are used and one common approach is to use the ¹³C NMR resonance of the organic solvent. For the two commonest NMR solvents, these have values relative to TMS of CDCl₃ at 77.5 ppm and dimethyl sulfoxide-*d*₆ at 39.5 ppm.

The ¹³C chemical shift of methane is at –2.3 ppm relative to TMS and from this base value it is possible to calculate shifts for other alkanes (and even substituted alkanes provided that the appropriate base shifts for the substituted methane are available) using the increment data given in Table 1 together with the following equation

$$\delta C = -2.3 + \sum Z_i + \sum S_j + \sum K_k \quad [1]$$

where *Z* denotes the substituent effects, *s* values are included to take into account steric effects and *K* allows for conformations of γ -substituents.

Methyl groups can have a fairly large range of shift values and these can also be predicted using substituent effects as shown in Table 2. Rules have been given by Grant and co-workers for calculating ¹³C chemical shifts of methyl and ring carbons in cyclohexanes.

The ¹³C NMR chemical shifts for cyclohexanes can be calculated using similar parameters to those for the aliphatic compounds above.

Much study has been devoted to halogenated alkanes including fluorinated compounds and predictive rules have been derived.

Alkenes

The ¹³C shifts for carbons of double bonds generally range from 80 to 160 ppm and they can again be estimated from empirical rules based on substituent effects. Thus the shifts of double bond carbons can be estimated from the equation

$$\delta = 123.3 + \sum z_i \quad [2]$$

where *z*₁ is an increment for substitution on the *ipso* carbon and *z*₂ is the effect of a substituent on the vicinal carbon. The substituent effects are given in Table 3.

Carbons involved in keto–enol tautomerism can experience large chemical shift differences according to the tautomer present. For example, for acetylacetone the carbonyl carbon resonates at 201.1 ppm in the keto form but is at 190.5 ppm in the enol form. Similarly, the carbon which is a methylene group in the keto form with a shift of 56.6 ppm moves to 99.0 ppm as an olefinic carbon in the enol form.

Ring strain can induce significant effects on ¹³C shifts. For example, the olefin carbons in cyclopropene are at 108.7 ppm, in cyclobutene they are at 137.2 ppm, in cyclopentene they appear at 130.8 ppm and in cyclohexene at 127.4 ppm.

Conjugation can also have large effects. The inner olefin carbon in butadiene is at 136.9 ppm, whilst the central carbon in allene is at 213.5 ppm with the outer carbon at 74.8 ppm.

Table 1 Estimation of the ¹³C chemical shifts in aliphatic compounds

Alkynes

Acetylene has a ¹³C shift of 71.9 ppm and the effects of substituents have been evaluated. These are given in Table 4.

Aromatic Hydrocarbons

Benzene has a chemical shift of 128.5 ppm and the 1-, 2- and 4a-positions of naphthalene have shifts of 128.0, 126.0 and 133.7 ppm, respectively. Well defined substituent effects on aromatic carbon shifts in benzene derivatives have been derived. These are calculated according to the equation

$$\delta = 128.5 + \sum z_i \quad [3]$$

and the substituent effects for *ortho*, *meta* and *para* positions are listed in Table 5. Similar data compilations are

available for naphthalene derivatives and for pyridines. The naphthalene substituent parameters can be used with a reasonable degree of success in other condensed ring hydrocarbons provided that the base values for a particular ring system are available. These have been given for a number of ring systems, including benzofuran, benzothiophene, benzimidazole, quinoline, isoquinoline and many others (see Further Reading).

The ¹³C shifts for purine and pyrimidine bases have also been measured and these form useful base values for studies of nucleosides, nucleotides and nucleic acids.

Oxygen-Containing Compounds

Alcohols show large chemical shifts according to the proximity of the oxygen to the measured carbon. Thus *n*-propanol has shifts of 64.2, 25.9 and 10.3 ppm for the carbons α , β and γ to the OH, respectively. Ethylene

glycol has a shift of 63.4 ppm, whilst glycerol has shifts of 64.5 and 73.7 ppm for the CH₂ and CH carbons, respectively. Trifluoroethanol, often used in protein and peptide NMR studies, has carbon shifts of 61.4 and 125.1 ppm for the CH₂ and CF₃ carbons, respectively, with ¹J_{CF} = 278 Hz and ²J_{CCF} = 35 Hz (see later). Ethers show similar substituent effects to alcohols. For cyclic ethers, ring strain again induces large chemical shift changes. Thus for ethylene oxide the CH₂ shift is 39.5 ppm whereas for the four-membered ring analogue the shift is 72.6 ppm.

Extensive data compilations are available for mono-saccharides and other sugars, including the tabulation by Bock.

Table 4 ¹³C Chemical shifts in alkynes (H-C_b≡C_a-X)

X	a	b
-H	71.9	71.9

Amines

The protonation of amines causes a shielding of carbons adjacent to the nitrogen except for branched systems, where some deshielding is often seen. The effect of protonation can be about -2 ppm at an α-carbon, -3 ppm at a β-carbon and up to -1 ppm at a γ-carbon. For example, the ¹³C shifts of ethylamine are 36.9 ppm (CH₂) and 19.0 ppm (CH₃) and these are shifted by -0.2 and -5.0 ppm, respectively, on protonation. Again, ring strain effects in cyclic amines are mirrored by large ¹³C shift effects.

Amino Acids

¹³C NMR data for amino acids have been tabulated extensively as these provide base values for studies of NMR spectra of peptides and proteins. The data compilation by Pretsch and co-workers is comprehensive, as are the results shown in the book by Wuthrich. Values are very pH dependent.

Other Functional Groups

Nitrile carbon shifts are in the range of 115–125 ppm whereas in isonitriles the shifts are around 155–165 ppm. In oximes, the carbon in the C=N bond appears around 150–160 ppm and in isocyanates the carbon shift is in the region of 120–125 ppm. For hydrazones with the functionality C=N-N, the ¹³C shifts are usually around 165 ppm. Methylene carbons adjacent to nitro groups generally appear near 70–80 ppm, and for methylene groups in nitrosoamines these appear around 45–55 ppm.

The SH group induces much smaller shift changes. The CH₂ resonance of carbons adjacent to a thiol group appear around 24–35 ppm according to the presence of other substituents and chain branching. Similar effects are seen in thioethers. Sulfoxides of the type RR'SO are chiral because of the pyramidal structure of the sulfoxide group and hence nonequivalence can be seen in the NMR spectra. Methylene carbons adjacent to sulfone groups appear around 55–65 ppm.

Carbonyl Carbons

For the fragment, Cβ–Cα–CO–Cα–Cβ, it is possible to estimate the carbonyl carbon chemical shift from the substituent effects given in **Table 6a** using the equation

$$\delta = 193.0 + \sum z_i \quad [4]$$

For carboxylic acids and esters, eqn [4] and **Table 6b** apply with a base shift of 166.0 ppm. For amides, the base shift is 165.0 ppm and the substituent effects in **Table 6c** are used.

Aldehyde carbons have a similar range of chemical shifts as ketones; for example, the shift for cyclohexane-1-aldehyde is 204.7 ppm. Cyclic ketones tend to be more deshielded than alicyclic ketones. For example, methyl ethyl ketone has a carbonyl shift of 207.6 ppm but cyclohexanone is at 209.7 ppm. The carbonyl group of lactones is highly shielded relative to other carbonyl carbons, with an upfield shift of around 20 ppm. Similarly, amide and lactam carbons are in the region of 165–175 ppm. The carbonyl carbons of anhydrides are also similarly shielded.

Coupling Constants

One-Bond J_{CH}

An extensive review of these is now available (see Further Reading). In general, these lie in the range 125–170 Hz but there are a number of values beyond this upper figure. The value can be estimated in substituted methanes of the type CHZ₁Z₂Z₃ using eqn [5] and the substituent effects in Table 7.

$$J_{CH} = 125.0 + \sum z_i \quad [5]$$

Two-Bond J_{CH}

These couplings can be small and vary considerably. For example, for the fragment ¹³C–C–H, J_{CH} is 1–6 Hz, for ¹³C=C–H it is 0–16 Hz and for ¹³C–(C=O)–H it is 20–50 Hz.

Three-Bond J_{CH}

These generally lie in the range 0–10 Hz but they depend on the dihedral angle in similar fashion to proton–proton coupling constants. Thus, when the ¹³C and ¹H are in bonds which are eclipsed, the coupling is around 6 Hz, when they are antiperiplanar, the coupling is about 9 Hz and when the bonds are at right-angles, the coupling drops to close to zero.

In alkenes, the three-bond *trans* coupling is always larger than the *cis* coupling for a pair of *cis*–*trans* isomers.

Typical values are 7–10 Hz for a *cis* coupling and 8–13 Hz for a *trans* coupling.

Three-bond couplings in aromatic molecules are generally around 7–10 Hz.

Other Couplings Involving ¹³C

One-bond ¹³C–¹³C couplings have a typical value of around 30–40 Hz in unstrained, unsubstituted systems. Ring strain causes a reduction in coupling constant, the value in cyclopropane, for example, being only 12.4 Hz. Couplings in conjugated systems tend to be higher, an extreme example being acetylene with a value of 171.5 Hz. ¹³C–¹³C coupling through two or three bonds can also be measured. Values are typically 1–5 Hz.

¹³C–¹⁹F coupling constants can also often be measured. The one-bond coupling is around 280–300 Hz depending on substituents, with the two-bond coupling also being of considerable magnitude, around 20 Hz. Longer range ¹³C–¹⁹F couplings are also observed, especially in aromatic and conjugated molecules. In fluorobenzene ¹ J_{CH} is 245.1 Hz, ² J_{CH} is 21.0 Hz, ³ J_{CH} is 7.8 Hz and ⁴ J_{CH} is 3.2 Hz.

In addition, a number of studies have made use of ¹³C–¹⁵N and ¹³C–³¹P coupling constants.

SPD	spectral power distribution

Introduction

The objective of colorimetry is the numerical description of colors in such a way that two objects with the same specification, for a given set of conditions, are always perceived to have the same color under those conditions. Any difference in the numerical descriptions of two similar, but nonidentical, colors should also correlate with the actual color difference evaluated by the observer. Such a system of color specification allows rapid and objective communication of color information, the specification of acceptable color tolerances, and the resolution of disagreements between observers. Colorimetry is widely used in many industries.

Color is not an intrinsic property of an object; its perception involves three important factors. The first is the light source. Light may enter the eye directly from the light source, for example, traffic lights or after the colorants present in a material selectively absorb or transmit part of the light illuminating it. Thus, the second important factor is the reflection or transmission of light by the object. This modified light enters the eye of the observer and stimulates the sensation, which is called the color of the material. The observer is, therefore, the third key factor that must be considered. For colorimetric purposes, numerical descriptions of each of these three factors are necessary.

CIE Illuminants

The numerical description of a light source is given by its spectral power distribution (SPD). This gives the emitted power within an unit wavelength interval as a function of the wavelength. For color measurement, a relative rather than an absolute SPD is adequate and it does not have to necessarily correspond to that of a real light source. The Commission Internationale de l'Éclairage (CIE) has proposed several so-called illuminants with defined SPDs specifically for colorimetric purposes. For example, the SPD of CIE illuminant A corresponds closely to that of

light from a tungsten filament lamp operating at a color temperature of 2856 K. The color temperature of a source is the operating temperature of an ideal black body emitter generating light with a color as close as possible to that of the source. Daylight is of course a major light source but is extremely variable. The CIE has defined the SPDs for a number of illuminants corresponding to typical phases of daylight, with color temperatures from 4000 to 25 000 K, the most common of which is CIE illuminant D65. For these illuminants, the label D represents daylight and the number of the color temperature in hundreds (65 = 6500 K). The CIE has also defined the SPDs of a number of F illuminants that represent different types of fluorescent light. The SPDs of some common CIE illuminants are illustrated in Figure 1.

Reflection or Transmission of Light by the Object

The numerical description of the reflection or transmission of light by an object is obtained by measuring the fraction of the incident light that is reflected or transmitted as a function of wavelength in the visible region, either continuously or for most colorimetric purposes at discrete equally separated wavelength values.

The reliability of colorimetric specifications is entirely dependent on the precision and accuracy of the reflectance or transmission data. Spectrophotometers must be

Figure 1 Relative spectral power distributions for CIE illuminants A, D65, and F7 (each normalized to the same relative power at 560 nm).

correctly calibrated and special care taken in preparing, manipulating, and mounting samples for measurement. There are particular problems with textured, lustrous, hygroscopic, and fluorescent samples. Different instruments have different illumination and light detection geometries, and comparison of colorimetric data should ideally be between those recorded using the same instrument geometries. The most common reflectance geometries involve: (a) illumination of the sample at an angle of 45° to the sample surface and detection of the reflected light at close to right angles (45/0), or (b) diffuse illumination from all directions, using an integrating sphere, and detection of the reflected light at close to perpendicular to the sample (d/8).

The Color Response of the Observer

The response of the observer is characterized by the data defining the CIE 1931 standard colorimetric observer (2° visual field), or the CIE 1964 supplementary colorimetric standard observer (10° visual field). These data were derived from experimental light mixing and color-matching experiments. To reproduce the colors of monochromatic spectral lights of given wavelength by additive mixing of three real primary lights, typically red, green, and blue, a match can only be achieved if the given spectral light in the test field is first desaturated somewhat, by illuminating it with a small amount of one of the primary lights, and then matching this resulting color by illumination of the adjacent field with a combination of the other two primaries. The matching condition is described by a colorimetric equation, for example,

$$C(\lambda) + \bar{r}(\lambda) [R] \equiv \bar{g}(\lambda) [G] + \bar{b}(\lambda) [B]$$

The above-mentioned equation is not an algebraic equation, the symbol $\equiv$ being intended only to signify the equivalence of two matching colors. This simply states that the spectral light of color C and wavelength λ , at the given power, can be matched by additive mixing of amounts $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ of the three respective primary lights $[R]$, $[G]$, and $[B]$. To avoid confusion among symbols, primary lights are designated inside square brackets. Thus, at any wavelength, the quantity of one primary required for a match is considered to be negative.

$$C(\lambda) \equiv -\bar{r}(\lambda) [R] + \bar{g}(\lambda) [G] + \bar{b}(\lambda) [B]$$

To avoid negative values, and for a number of other reasons, the color-matching functions $\bar{r}(\lambda)$, $\bar{g}(\lambda)$, and $\bar{b}(\lambda)$ were transformed into a set $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ based on nonreal primary lights $[X]$, $[Y]$, and $[Z]$. These correspond to imaginary 'red,' 'green,' and 'blue' primaries of greater purity than any spectral lights. The following color-matching equation, based on averaging the results

for a number of observers, is then the necessary numerical description of the human color response in matching the colors of light at each wavelength of the visible spectrum, each with unit power.

$$C(\lambda) \equiv \bar{x}(\lambda) [X] + \bar{y}(\lambda) [Y] + \bar{z}(\lambda) [Z]$$

The values $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ are called the spectral color-matching functions or tristimulus values for the standard observer.

The addition of all the visible wavelengths, at the same power, would produce the so-called equal energy white light (EEW).

$$\begin{aligned} \text{EEW} \equiv \sum C(\lambda) &\equiv \sum (\bar{x}(\lambda)) [X] \\ &+ \sum (\bar{y}(\lambda)) [Y] + \sum (\bar{z}(\lambda)) [Z] \end{aligned}$$

The relative units for the primaries $[X]$, $[Y]$, and $[Z]$ are chosen such that

$$\sum \bar{x}(\lambda) = \sum \bar{y}(\lambda) = \sum \bar{z}(\lambda)$$

so that the equal energy white would be matched by equal amounts of the three primaries $[X]$, $[Y]$, and $[Z]$.

The CIE 1931 standard observer was used for over 20 years with considerable success, but it became clear that the measurements made with this data did not always correspond with visual assessments. In the 1950s, spectral color-matching functions $\bar{r}_{10}(\lambda)$, $\bar{g}_{10}(\lambda)$, and $\bar{b}_{10}(\lambda)$ were determined using a visual field subtending 10° rather than 2° at the eye. As before, these color-matching functions also always had one negative value and they were transformed into an all positive set $\bar{x}_{10}(\lambda)$, $\bar{y}_{10}(\lambda)$, and $\bar{z}_{10}(\lambda)$ based on the virtual primaries $[X_{10}]$, $[Y_{10}]$, and $[Z_{10}]$. These data were the basis for the CIE 1964 supplementary standard observer. This standard observer does give a better correlation of the colorimetric results with actual color-matching observations and is more widely used today. The two sets of spectral color-matching functions are compared in **Figure 2**. These can also be expressed as normalized chromaticity coordinates. For example, for the 1964 supplementary standard observer, the chromaticity coordinates $x_{10}(\lambda)$, $y_{10}(\lambda)$, and $z_{10}(\lambda)$ (symbols without a bar) are given by

$$x_{10}(\lambda) = \frac{\bar{x}_{10}(\lambda)}{\bar{x}_{10}(\lambda) + \bar{y}_{10}(\lambda) + \bar{z}_{10}(\lambda)}$$

$$y_{10}(\lambda) = \frac{\bar{y}_{10}(\lambda)}{\bar{x}_{10}(\lambda) + \bar{y}_{10}(\lambda) + \bar{z}_{10}(\lambda)}$$

$$z_{10}(\lambda) = \frac{\bar{z}_{10}(\lambda)}{\bar{x}_{10}(\lambda) + \bar{y}_{10}(\lambda) + \bar{z}_{10}(\lambda)}$$

and

$$x_{10}(\lambda) + y_{10}(\lambda) + z_{10}(\lambda) = 1$$

Figure 2 Comparison of the CIE 1931 color-matching functions $\bar{x}_2(\lambda)$, etc., with the CIE 1964 values, $\bar{x}_{10}(\lambda)$, etc.

The well-known CIE chromaticity diagram is a graph of the chromaticity coordinates of the spectral colors, y versus x , or y_{10} versus x_{10} .

The CIE colorimetric system consists of recommendations for the SPDs of various illuminants, and of the color-matching functions or chromaticity coordinates for observers using visual fields subtending angles of 2° or 10° , respectively. The color-matching functions represent the relative amounts of the three virtual primaries $[X]$, $[Y]$, and $[Z]$ (or $[X_{10}]$, $[Y_{10}]$, and $[Z_{10}]$) whose additive mixture reproduces the colors of given monochromatic spectral lights. It applies for spectral lights at unit power. In terms of the color-matching equation, at each wavelength

$$C(\lambda) \equiv \bar{x}(\lambda) [X] + \bar{y}(\lambda) [Y] + \bar{z}(\lambda) [Z]$$

This is the necessary numerical description of the color response of an average human observer with normal color vision.

The Basis of Color Specification Using the Standard Observer

The above-mentioned color-matching equation states that a match of a spectral light, of wavelength λ at unit power, is possible by mixing the three primary lights $[X]$, $[Y]$, and $[Z]$ in the amounts $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$. The perceived color of an object is a consequence of all the visible wavelengths of light entering the eye. For each of these wavelengths, the incident power is given by the product of the spectral power of the light source at each wavelength, $S(\lambda)$ and the reflectance or transmittance factor (R or T) for the object, for example, $S(\lambda) \cdot R(\lambda)$. The

equation for matching the color of such a spectral component is

$$\begin{aligned} S(\lambda) \cdot R(\lambda) \cdot C(\lambda) &\equiv (S(\lambda) \cdot R(\lambda) \cdot \bar{x}(\lambda)) [X] \\ &\quad + (S(\lambda) \cdot R(\lambda) \cdot \bar{y}(\lambda)) [Y] \\ &\quad + (S(\lambda) \cdot R(\lambda) \cdot \bar{z}(\lambda)) [Z] \end{aligned}$$

Since the perceived color of the object is that produced from the combined effects of all the component wavelengths, the tristimulus values for this color are calculated by summation.

$$\begin{aligned} Color &\equiv \sum (S(\lambda) \cdot R(\lambda) \cdot C(\lambda)) \\ &\equiv \sum (S(\lambda) \cdot R(\lambda) \cdot \bar{x}(\lambda)) [X] \\ &\quad + \sum (S(\lambda) \cdot R(\lambda) \cdot \bar{y}(\lambda)) [Y] \\ &\quad + \sum (S(\lambda) \cdot R(\lambda) \cdot \bar{z}(\lambda)) [Z] \end{aligned}$$

This is the numerical description of the color perceived by the observer and is usually written

$$Color \equiv X[X] + Y[Y] + Z[Z]$$

where X , Y , and Z represent the respective summations and are called the tristimulus values. In the CIE system, the tristimulus values are normalized so that the light source (illuminant) always has a Y tristimulus value equal to 100. This is done using a normalization constant k , defined in such a way that for the illuminant light

$$\begin{aligned} X &= k \sum (S(\lambda) \cdot \bar{x}(\lambda)) \\ Y &= 100 = k \sum (S(\lambda) \cdot \bar{y}(\lambda)) \\ Z &= k \sum (S(\lambda) \cdot \bar{z}(\lambda)) \end{aligned}$$

Thus, for a given polychromatic light source

$$k = \frac{100}{\sum (S(\lambda) \cdot \bar{y}(\lambda))}$$

The tristimulus values for a given color are therefore

$$\begin{aligned} X &= k \sum (S(\lambda) \cdot R(\lambda) \cdot \bar{x}(\lambda)) \\ Y &= k \sum (S(\lambda) \cdot R(\lambda) \cdot \bar{y}(\lambda)) \\ Z &= k \sum (S(\lambda) \cdot R(\lambda) \cdot \bar{z}(\lambda)) \end{aligned}$$

and provide the required numerical description of the perceived color.

The key parameters in the calculations are those for the three factors that determine the perceived color of an object, namely: (1) $S(\lambda)$, the relative SPD of the selected illuminant, (2) $R(\lambda)$, the reflectance factor (or the transmission factor) of the object, and (3) $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$, the spectral color-matching functions of the chosen

standard observer. Because of the above-mentioned normalization procedure with k , the calculation of the tristimulus values of a color can be carried out with the relative rather than the absolute SPD of the illuminant, the percentage reflectance rather than the fractional reflectance factor (provided the value of the normalization constant k is divided by 100), and with the spectral color-matching functions or the spectral chromaticity coordinates of the selected standard observer.

The CIE recommends measurement of the reflectance factors from 380 to 780 nm, with a wavelength increment of 5 nm. This is not possible with many abridged spectrophotometers that only have a range from 400 to 700 nm, with measurements at intervals of 10 or even 20 nm. For the calculation of X , Y and Z with such instruments, reasonable precision is achieved by appropriate weighting of the color-matching functions. The American Society for Testing and Materials also provides extensive tables of values of weighting functions, each color-matching function multiplied by $S(\lambda)$, for both CIE standard observers and a variety of illuminants, for different wavelength intervals. These functions ensure that the tristimulus values are always the same independent of the wavelength interval used for the calculation.

The sole purpose of the CIE colorimetric system is to establish whether two objects have identical perceived colors, when viewed by the standard observer under conditions corresponding to those of the selected illuminant. If the respective tristimulus values of the colors of two samples are equal, then an average observer will judge the samples to have identical colors for the given viewing conditions. It is vital to remember that the tristimulus values provide no reliable information on the degree of perceived color difference between two samples.

Illuminant Metamerism

The common phenomenon of illuminant metamerism arises when two samples, which have matching colors under one source of light, say daylight, have different perceived colors under another light source such as tungsten light. Such metamerism involves two objects with different reflection spectra, giving identical colors and tristimulus values for one CIE illuminant, but different colors when the illumination is changed. The only way in which illuminant metamerism can be avoided is if the two samples are colored with identical colorants and thus have matching colors with identical reflection spectra. Even for such nonmetameric samples, the perceived colors change when the illumination is changed, but they change in exactly the same way and the colors remain matched. This often goes unnoticed because of the rapid adaptation of the eye.

The CIE XYZ Color Space

The tristimulus values X , Y , and Z of any color can be represented by a single point on a 3-D graph with mutually perpendicular axes. All real colors will have their coordinates within a boundary defining this XYZ color space. The color difference between two samples then corresponds to the distance between the two points for their respective coordinates. A major problem with the CIE XYZ system is that the corresponding color space is not visually uniform. This means, for example, that two greens, which are just perceptibly different in color, give a considerably larger distance between their positions in the color space than a pair of two red or blue samples, which have also been judged to have the same color difference as the pair of greens. Thus, a single tolerance cannot be specified for all colors. This defeats a major objective of having a color measurement system. This problem prompted the search for a more visually uniform color space. Despite many attempts, the ideal color space has proved to be very elusive. Those which have been recommended are based on modification of the XYZ system.

The CIELAB (1976) Color Space

The CIELAB color space was developed from earlier attempts to transform the X , Y , and Z tristimulus values into coordinates which would provide a more visually uniform color space based on the LAB concept, as described in Hering's color vision theory. Although the cone cells in the eye respond roughly to red, green, and blue light, the nerve impulses sent to the visual cortex are signals in terms of lightness (L^*) and opponent colors, red–green (a^*) and yellow–blue (b^*). The CIELAB system was first recommended in 1976 and became very popular for color and color difference specification. The value of L^* for a given color varies between 100 (perfect white) and 0 (perfect black), and gives a measure of the lightness of the color. The value of a^* is a measure of the red–green character of the color, with positive values for red shades and negative values for green. The value of b^* gives the yellow–blue character with positive values for yellow shades and negative for blues (see **Figure 3**). The values of L^* , a^* , and b^* are usually calculated from the tristimulus values using the 1964 supplementary standard observer, each value being first divided by the corresponding tristimulus value of the selected illuminant (X_m , Y_m and Z_m).

$$L^* = 116(Y/Y_m)^{1/3} - 16$$

$$a^* = 500 \left((X/X_m)^{1/3} - (Y/Y_m)^{1/3} \right)$$

$$b^* = 200 \left((Y/Y_m)^{1/3} - (Z/Z_m)^{1/3} \right)$$

Figure 3 The CIELAB color space showing the parameters L^* , a^* , b^* , C_{ab} , and h_{ab} of a given color and the ΔE_{ab}^* color difference.

The cube root functions for (X/X_n) , (Y/Y_n) , and (Z/Z_n) are replaced by other forms if their values are equal to or less than 0.008856, that is, for very dark shades.

Quantitative Color Differences Using CIELAB

The values of L^* , a^* , and b^* for two different colors allow calculation of the color difference between them ΔE_{ab}^* (the distance between the points for their respective coordinates in the CIELAB color space) according to the law of Pythagoras.

$$\Delta E_{ab}^* = \sqrt{\Delta L^{*2} + \Delta a^{*2} + \Delta b^{*2}}$$

where $\Delta L^* = L^*(\text{sample}) - L^*(\text{standard})$ with similar definitions for Δa^* and Δb^* . Such a measurement of color difference is useful to establish if a color is acceptable relative to a standard, or to determine the degree of metamerism of a single sample under two different illuminants. In measuring small color differences, it is essential that the data are reproducible, and that the color measurements provide true color differences and not differences caused by variations in the nature and presentation of the sample or in the operation of the instrument. The CIELAB color space, although considerably more visually uniform than the XYZ space, is not perfect and the value of ΔE_{ab}^* does not always correspond closely to the color difference between samples evaluated by visual examination.

Hue, Chroma, and Lightness

The position of the point representing a color can also be defined using cylindrical coordinates. Using such

coordinates for the CIELAB space, the exact position of a point will be defined by a height above $L^* = 0$, a radial distance from the central vertical black–white axis (chroma, C_{ab}^*), and by an angle relative to some initial chroma radius (hue angle, h_{ab} measured from the positive a^* axis). A human observer invariably characterizes color differences in terms of differences in hue, chroma or saturation, and lightness. These cylindrical coordinates thus correspond more closely to the way colors are described. The relationships between C_{ab}^* or h_{ab} , a^* and b^* , given in the following text, are illustrated in **Figure 3**.

$$C_{ab}^* = \sqrt{a^{*2} + b^{*2}} \quad \tan(h_{ab}) = \frac{b^*}{a^*}$$

The values of h_{ab} vary from 0° (a^* axis, red) through 90° (b^* axis, yellow), 180° (negative a^* axis, green), 270° (negative b^* axis, blue), up to 360° (a^* axis).

For colors that are quite similar, and whose coordinates place them close together in the color space, it is possible to define a difference in chroma ΔC_{ab}^* and in hue ΔH_{ab}^* . The value of ΔC_{ab}^* is given by $C(\text{sample}) - C(\text{standard})$. The value of ΔH_{ab}^* is calculated by difference, based on the Pythagoras theorem.

$$\Delta H_{ab}^* = \sqrt{\Delta E_{ab}^{*2} - \Delta L^{*2} - \Delta C_{ab}^{*2}}$$

The human eye is more sensitive to differences in hue than of chroma or lightness and stricter tolerances will be required for ΔH_{ab}^* than for ΔL^* and ΔC_{ab}^* .

There are approximately 20 different systems for color difference specification. This gives an indication of the problem of correlating measured color differences with perceived visual differences. Numerical color differences from one system of calculation cannot be transformed into color differences for another system. The majority of color difference systems are now of historical interest since the recommendation of CIELAB. This system is not perfect, however, which complicates the establishment of tolerances. Tolerances for acceptability are obviously less stringent than those for perceptibility. In the CIELAB color space, acceptability and perceptibility tolerances vary with position. This means that individual CIELAB color tolerances have to be established for a number of production colors, a task which is time consuming and demanding.

The CMC System

The CMC system was originally developed by R. McDonald and later recommended by the Color Matching Committee (CMC) of the Society of Dyers and Colorists with only minor modifications. For a large number of different colors, with multiple samples of each color, the values of L^* , C_{ab}^* , and H_{ab}^* for each color were

plotted on a 3-D graph. This gave a series of points close to the coordinates for each target color but closely scattered around it in all directions. An ellipsoid was drawn through these points, with the coordinates for the target at its centre, and whose surface enclosed the points for those samples judged to be acceptable matches with the target by at least 50% of the observers. The size of this acceptability ellipsoid is defined by the lengths of its three semiaxes S_L , S_C , and S_H in the L^* , C_{ab}^* , and H_{ab}^* directions, respectively. These represent the acceptable tolerances for lightness (S_L), chroma (S_C), and hue (S_H). These tolerances vary as the coordinates of the standard color changes, but electronic computation of S_L , S_C , and S_H easily handles the rather complex equations.

$$S_L = \frac{0.040975L^*}{1 + 0.01765L^*} \quad \text{for } L^* < 16$$

$$S_L = 0.511 \quad \text{for } L^* < 16$$

$$S_C = \frac{0.0638C_{ab}^*}{1 + 0.0131C_{ab}^*} + 0.638$$

$$S_H = S_C \{ (T \cdot f) + 1 - f \} \quad \text{where } f = \sqrt{\frac{C_{ab}^{*4}}{1900 + C_{ab}^{*4}}}$$

and

$$T = 0.36 + |0.4 \cos(b_{ab} + 35)| \quad \text{for } b_{ab} < 164^\circ \text{ or } > 345^\circ$$

or

$$T = 0.56 + |0.2 \cos(b_{ab} + 168)| \quad \text{for } b_{ab} > 164^\circ \text{ but } < 345^\circ.$$

The values of S_H are usually lower than those of S_C and S_L because of the lower observer tolerance to hue differences. The observed variations in the ellipsoid semiaxes thus reflect the visual nonuniformity of the CIELAB color space. If it was visually uniform, the acceptability volumes would all be spherical and of equal size throughout the color space. The CMC color difference is defined by

$$(\Delta E_{CMC})^2 = \left(\frac{\Delta L^*}{l \cdot S_L} \right)^2 + \left(\frac{\Delta C_{ab}^*}{c \cdot S_C} \right)^2 + \left(\frac{\Delta H_{ab}^*}{S_H} \right)^2$$

This equation gives the coordinates of points lying on the surface of a 3-D ellipsoid, with semiaxes with lengths of $l \cdot S_L$, $c \cdot S_C$, and S_H and with $\Delta E_{CMC} = 1.0$ (Figure 4). The weighting factors l and c (both > 1) for S_L and S_C in the respective denominators of the CMC color difference equation indicate the lesser importance of the tolerances S_L and S_C relative to S_H . This allows variations of these weighting factors for different situations and different substrates. The CMC recommends $l = 1$ and $c = 1$ when evaluating perceptibility differences, but $l = 2$ and $c = 1$ for differences in acceptability for textiles. This is in line with the greater visual tolerance of lightness differences in color matching. A value of $\Delta E_{CMC} = 1.0$ thus becomes

Figure 4 Illustration of a CMC acceptability ellipsoid showing the three semiaxes S_L , S_C , and S_H .

the sole color acceptability tolerance for all colors. A pass/fail evaluation based on a single color difference value has obvious advantages in commercial color matching. The CMC system has become an international standard in many countries.

In addition to the CMC color difference equation, the CIE have recommended an alternative correction to the CIELAB color space. The CIE-94 color difference equation is identical to the CMC equation, but the values of S_L , S_C , and S_H are calculated using simpler linear equations. There are also other systems but any one is not particularly superior to the others. Details of the more recent CIE DE2000 color difference formula can be found in Schanda's book listed under Further Reading.

Applications of Colorimetry

Quality Control

Manufacturers, who make colored products such as textiles, paints, paper, and cosmetics, invariably want to produce multiple lots of the same product, and often repeat lots on demand. Different lots invariably have small variations of color. Many manufacturers are often required by contract to produce a particular colored product with color coordinates within certain tolerances. Thus, colorimetry is an essential tool for quality control and the resolution of observer differences.

Shade Sorting for Textile Fabrics

For a large number of rolls of the same colored fabric, it is common for these to exhibit slight but visible color differences. The objective of shade sorting is to identify and group together rolls of fabric with a negligible color difference, from which panels can be cut and assembled into the required article without any objectionable color differences at the seams between adjacent panels. Visual

color sorting is not particularly reliable since the same person often produces different sorting results from day to day for the same set of samples. A number of shade-sorting systems, based on colorimetric measurements and established color difference tolerances, help to minimize this problem. In shade sorting, the 3-D color space is divided into rectangular boxes or dodecahedra, the size of which depends on the desired tolerances say in hue, chroma, and lightness. Colors with their coordinates inside a given box can be processed together. In color clustering, a grid is not used, but algorithms have been developed, which group together colors that have a given minimal color difference. Color tapering arranges samples in a series of gradually changing color so that adjacent samples have a minimal color difference. These techniques are only reliable if the colorimetric data are precise.

Colorant Formulation

The objective of colorant formulation is to calculate the amounts of colorants required to color a given material with exactly the required shade. Before 1970, this was done in the laboratory by visual comparisons and was often a matter of trial and error. Today, match prediction depends on instrumental color measurement and computer algorithms.

Spectrophotometric matching

Some formulation procedures attempt to match the reflection spectrum of the sample using the Kubelka–Munk equation relating the absorption (K) and scattering coefficients (S) for each colorant and the concentrations of the colorants in the sample with its overall reflectance. Simple additivity is assumed. For a mixture of i colorants in a sample, the global Kubelka–Munk K/S value at a given wavelength is

$$\frac{K}{S} = \frac{K_{\text{sub}} + \sum(K_i C_i)}{S_{\text{sub}} + \sum(S_i C_i)} = \frac{(1 - R_{\infty})^2}{2R_{\infty}}$$

where K and S are the respective values of the absorption and scattering coefficients at unit concentration of the various colorants (i) and of the noncolored substrate (sub). C_i is the concentration of each colorant. R_{∞} is the reflectance of a sample that is sufficiently thick to prevent light transmission through it.

Since both K_i and S_i must be known for all the colorants to be used to achieve the match this is known as the two-constant method. It is required for color-matching paints where both the white base, for example, titanium dioxide, and the colored pigments are responsible for light scattering. The procedures require considerable preparation and are quite involved.

In dyed textiles and paper, most dyes are molecularly dispersed in the fibers and do not contribute significantly to light scattering. Their values of S_i are negligible. The global value of K/S for the colored sample with $S_i=0$ then becomes

$$\begin{aligned} \frac{K}{S} &= \frac{K_{\text{sub}} + \sum(K_i C_i)}{S_{\text{sub}}} = \left(\frac{K}{S}\right)_{\text{sub}} + \sum\left(C_i \frac{K_i}{S_{\text{sub}}}\right) \\ &= \left(\frac{K}{S}\right)_{\text{sub}} + \sum(C_i a_i) \end{aligned}$$

and involves only one constant K_i .

The value of K/S for the noncolored material is the value $(K/S)_{\text{sub}}$, when all the C_i values are zero. The values of a_i are the slopes of the calibration graphs of K/S versus C_i for a series of samples colored with different concentrations of an individual colorant. The values vary with wavelength. If the color of a sample is to be matched with say three dyes, the above-mentioned equation can be solved for C_1 , C_2 , and C_3 by calculations at three different wavelengths. Calculations at all wavelengths in the visible region using matrix algebra are superior.

Tristimulus matching

The objective of tristimulus matching is to generate a colorant formula that will result in a color whose tristimulus values match those of the target color for the chosen CIE illuminant and standard observer. This metameric match will invariably only be acceptable for the given viewing conditions. The same numerical technique can also be used to modify the formula and to calculate any shading additions.

From arbitrary or pre-estimated values of the three colorant concentrations C_1 , C_2 , C_3 and the Kubelka–Munk equation, the reflectance values are calculated at say 16 equally spaced wavelengths from 400 to 700 nm. The predicted reflection spectrum then allows calculation of the tristimulus values of the anticipated match X_m , Y_m , and Z_m for the selected illuminant and standard observer and calculation of the tristimulus value differences $dX = X_{\text{std}} - X_m$, $dY = Y_{\text{std}} - Y_m$, $dZ = Z_{\text{std}} - Z_m$. If dX , dY , and dZ are larger than acceptable, a match is not possible. It is then necessary to calculate the concentration changes dC_1 , dC_2 , and dC_3 that will eliminate the tristimulus value differences between the target and the match. The total change of each tristimulus value can be written with a term for the effect of each dye concentration.

$$dX = \left(\frac{\partial X}{\partial C_1}\right)dC_1 + \left(\frac{\partial X}{\partial C_2}\right)dC_2 + \left(\frac{\partial X}{\partial C_3}\right)dC_3$$

$$dY = \left(\frac{\partial Y}{\partial C_1}\right)dC_1 + \left(\frac{\partial Y}{\partial C_2}\right)dC_2 + \left(\frac{\partial Y}{\partial C_3}\right)dC_3$$

$$dZ = \left(\frac{\partial Z}{\partial C_1}\right)dC_1 + \left(\frac{\partial Z}{\partial C_2}\right)dC_2 + \left(\frac{\partial Z}{\partial C_3}\right)dC_3$$

This is solved for dC_1 , dC_2 , and dC_3 by matrix algebra. The nine values such as dX/dC are calculated as follows.

$$\begin{aligned} \frac{dX}{dC_1} &= \sum \left(S(\lambda) \cdot \bar{x}(\lambda) \cdot \frac{dR(\lambda)}{dC_1} \right) \\ &= \sum \left(S(\lambda) \cdot \bar{x}(\lambda) \cdot \frac{dR(\lambda)}{d(K/S)_\lambda} \cdot \frac{d(K/S)_\lambda}{dC_1} \right) \end{aligned}$$

For nonscattering colorants, the value of $dR/d(K/S)$ is the inverse of the differential of the Kubelka–Munk equation.

$$\frac{dR}{d(K/S)} = \frac{2R^2}{(R^2 - 1)}$$

The new values of the concentrations (New C_i = Old $C_i + dC_i$) are then used to calculate a revised anticipated reflection spectrum and so on until the values of dX , dY , and dZ are negligibly small.

The earlier calculation procedures, based on spectrophotometric or tristimulus matching, serve to illustrate some of the basic principles of colorant formulation. Computer colorant formulation is highly dependent on the colorimetric data for the target, for the calibration samples with individual colorants, and for the sample colored with the predicted formula. Such measurements must be reliable and reproducible.

A variety of more complex mathematical techniques for color matching are known and used in commercial software for this purpose. Computer-assisted colorant formulation, however, is occasionally unsatisfactory, even when the coloration process and all the data are reliable.

Some of the problems come from the invalidity of the assumptions made in the calculation procedures.

The availability of high-speed computers has provided a powerful technology for match prediction. Further developments involving neural networks, artificial intelligence, and the modeling of appearance will be even more powerful provided that they are accompanied by advances in coloration and colorimetric reproducibility.

L^*, C^*, h°	values in the CIE $L^* C^* h^\circ$ system
$r(\lambda), g(\lambda), b(\lambda)$	Guild/Wright colour-matching functions
$R(\lambda)$	reflectance
R, G, B	values in the RGB system
$S(\lambda)$	spectral power distribution of light source
$\bar{x}(\lambda), \bar{y}(\lambda), \bar{z}(\lambda)$	weighting functions replacing $\bar{r}(\lambda), \bar{g}(\lambda), \bar{b}(\lambda)$ in the XYZ system
X, Y, Z	tristimulus values in the XYZ system
ΔE_{ab}	distance function in the CIE $L^* a^* b^*$ system

Colorimetry is the science of the measurement of colour. It involves the replacement of subjective responses, such as ‘light blue’, ‘rich dark purple’, ‘bright gold’, with an objective numerical system. This study began with the work of Young, Helmholtz and Maxwell in the early nineteenth century, who recognized the principles of additive and subtractive colour mixing and proposed the trichromatic nature of human colour vision. The science began to be formalized in 1931, when the Commission Internationale de l’Eclairage (CIE) recommended a system of colour specification based on the three tristimulus values X , Y and Z . The current CIE reference document relating to colorimetry is CIE Publication 15: 2004 (Colorimetry, 3rd Edition); for more practical information on colorimetric measurement, ASTM document E308–96 should be consulted.

Illumination, Object, Observer

Three things contribute to our perception of the colour of an object: the nature of the illumination, the optical properties of the object itself and the response of the human eye (Figure 1). The nature of the illumination can be characterized by the spectral power distribution $S(\lambda)$ of the light source, the relative intensity of the illumination at each wavelength in the visible spectrum. The object reflects a certain fraction of the incident light, and this can be characterized by the reflectance spectrum $R(\lambda)$. The intensity of light entering the eye, $I(\lambda)$, is the product of these terms. Thus to measure colour and to specify colour by numbers, it is necessary to specify each of these three components of the colour trio. In 1931, the CIE recommended standard illuminants for use in colorimetry, published data representing the standard observer and recommended standard optical geometries for use in colour-measuring instruments.

Standard Illuminants (A, C, D65, F)

In 1931 the CIE recommended three standard sources and illuminants (A, B and C) where a source is a physically realizable light source and an illuminant is a table of data (spectral power distribution) representing a source. A is intended to represent an incandescent tungsten filament lamp (colour temperature 2856 K); B and C may be produced by filtering the light from source A to produce a representation of noon sunlight (B) or average daylight (C). More recently, the CIE has recommended the D series as illuminants only, representing

Figure 1 How colour reaches the eye.

Figure 2 Relative spectral power distributions of common CIE illuminants.

daylight in various phases. D75 (colour temperature 7500 K) represents north sky daylight, D65 (colour temperature 6500 K) represents average daylight and D55 (colour temperature 5500 K) represents sunlight plus skylight. D65 is now the reference illuminant for use in colorimetry (although the graphic arts industry tends to prefer D55) and so it should be included in any colour specification. Unfortunately, illuminant D65 is not realizable in practice, and so colour-matching cabinets generally contain a daylight simulator (a filtered fluorescent lamp). A further series of fluorescent lamps, the F series, were also defined, although none is specified as a standard illuminant. There are three types: normal, broad-band and three-band. The most important are F2 (normal, known as 'cool white'), F7 (broad-band, known as 'artificial daylight' and commonly used for colour matching) and F12 (three-band, with high energy efficiency, and so often used in shops). **Figure 2** shows the relative spectral power distribution of the more commonly used illuminants.

Standard Observers (2°, 10°)

The experiments that established the basis of colorimetry were carried out separately by J. Guild at the National Physical Laboratory (UK) and W.D. Wright at Imperial College London in a famous series of experiments in the late 1920s. These experiments were dedicated to characterizing the response of the human eye to different wavelengths of light, and were carried out by colour matching using red, green and blue lights. A set of red, green and blue light sources are often called primary sources since the appearance of any one of the sources cannot be matched by blending together light from the other two. A possible experimental arrangement is

Figure 3 Possible arrangements of Guild's and Wright's experiments.

illustrated in **Figure 3**. Each worker used several observers (Guild 7 and Wright 10) who adjusted the mixture of light from three primaries until it matched the appearance of the monochromatic light.

These early experiments were carried out using the central area of the retina, the fovea. This region contains the highest concentration of colour-sensitive cells and occupies the central 2° field (based on the angle to the line of sight, drawn from the centre of the lens to the foveal pit). The standard observer derived from Guild's and Wright's experiments is therefore known as the 2° standard observer (1931). The colour matching functions $\bar{r}(\lambda)$, $\bar{g}(\lambda)$ and $\bar{b}(\lambda)$ represent the amounts of light from the red, green and blue primaries, in tristimulus units, needed to match unit intensity of light with a narrow band of wavelengths centred on λ . Tristimulus units are defined such that a mixture of equal units of the red, green and blue primaries will match an equal-energy white. The values of the colour-matching functions are normalized so that there is an equal area under each of the spectral curves. The values are plotted against wavelength in **Figure 4**.

Figure 4 Guild's and Wright's colour-matching functions.

It was found that not all the colours produced by monochromatic light could be matched by a simple additive mixture of light from three primaries. For some wavelengths, it was necessary to add light from one of the primaries to the monochromatic light, reducing the colour saturation of the monochromatic light. The appearance of the desaturated mixture could then be matched by a combination of the other two primaries. When this occurs, the amount of the primary added to the monochromatic light appears as a negative number in the colour specification.

Later workers observed that although the fovea is the region most sensitive to colour, most everyday objects occupy a larger area of the retina. The 10° standard observer (1964) was thus derived in a similar manner and is now the preferred observer function. The true cone sensitivities were not measured directly until 1979, but correspond very well to those expected from the colour-matching functions found by Guild and Wright.

RGB Specification

The RGB system of colour specification was based on the trichromatic theory of colour vision and the colour-matching experiments carried out by Guild and Wright. It had been suggested by Maxwell in 1860 that if the specifications of the red, green and blue lamps used in such experiments were known, then the amounts of each light required to match a sample colour would provide a numerical specification of that colour. These amounts may be found either by passing the light from the sample through filters matching the RGB primaries or by calculation from the reflectance values of the sample at a

series of wavelengths through the visible spectrum:

$$\begin{aligned}
 R &= k[I(\lambda_1) \bar{r}(\lambda_1) + I(\lambda_2) \bar{r}(\lambda_2) + \dots] \\
 \text{or } R &= k \sum_{\lambda=380}^{\lambda=780} I(\lambda) \bar{r}(\lambda) \\
 G &= k[I(\lambda_1) \bar{g}(\lambda_1) + I(\lambda_2) \bar{g}(\lambda_2) + \dots] \\
 \text{or } G &= k \sum_{\lambda=380}^{\lambda=780} I(\lambda) \bar{g}(\lambda) \\
 B &= k[I(\lambda_1) \bar{b}(\lambda_1) + I(\lambda_2) \bar{b}(\lambda_2) + \dots] \\
 \text{or } B &= k \sum_{\lambda=380}^{\lambda=780} I(\lambda) \bar{b}(\lambda) \quad [1]
 \end{aligned}$$

Although RGB values are a valid representation of the colour of an object viewed under specified conditions, for practical reasons these values are rarely used. For a significant proportion of colours one of the three values is negative, and this was considered a distinct disadvantage.

XYZ Specification (1931)

The XYZ system of colour specification was recommended by the CIE in 1931 and was closely based on the RGB system. The difference lies in the fact that R , G and B were real light sources of known specifications. X , Y and Z are theoretical sources which are more saturated than any real light source and allow matching of any real colour using positive amounts of the three primary sources. The X , Y and Z stimuli are defined so that:

- The XYZ tristimulus values of all real colours are positive.
- The Y tristimulus value is proportional to the luminance.
- A mixture of equal amounts of X , Y and Z has the same colour appearance as an equal-energy white.
- The X , Y , Z values of the visible colours have the widest possible range of values.
- The X stimulus represents a red more saturated than any spectral red.
- The Y stimulus represents a green more saturated than any spectral green.
- The Z stimulus represents a blue more saturated than any spectral blue.

X , Y , Z values for the 2° observer may be calculated from RGB values using the equations:

$$\begin{aligned}
 X &= 0.49R + 0.31G + 0.20B \\
 Y &= 0.17697R + 0.81240G + 0.01063B \\
 Z &= 0.00R + 0.01G + 0.99B \quad [2]
 \end{aligned}$$

Alternatively, XYZ values may be calculated from reflectance values using similar equations to those for RGB, but using weighting functions $\bar{x}(\lambda)$, $\bar{y}(\lambda)$ and $\bar{z}(\lambda)$ in place of $\bar{r}(\lambda)$, $\bar{g}(\lambda)$ and $\bar{b}(\lambda)$. The CIE nomenclature is to denote the 10° observer function with a subscripted '10' (eqn [3]). The XYZ system is an improvement over the RGB system in that it eliminates negative numbers in colour specification. However, it is still based on the mixing of coloured lights and not on the visual appreciation of colour. In particular, the visual colour difference between two samples is not linearly related to the difference in XYZ values:

$$\begin{aligned} X_{10} &= k[I(\lambda_1) \bar{x}_{10}(\lambda_1) + I(\lambda_2) \bar{x}_{10}(\lambda_2) + \dots] \\ \text{or } X_{10} &= k \sum_{\lambda=380}^{\lambda=780} I(\lambda) \bar{x}_{10}(\lambda) \\ Y_{10} &= k[I(\lambda_1) \bar{y}_{10}(\lambda_1) + I(\lambda_2) \bar{y}_{10}(\lambda_2) + \dots] \\ \text{or } Y_{10} &= k \sum_{\lambda=380}^{\lambda=780} I(\lambda) \bar{y}_{10}(\lambda) \\ Z_{10} &= k[I(\lambda_1) \bar{z}_{10}(\lambda_1) + I(\lambda_2) \bar{z}_{10}(\lambda_2) + \dots] \\ \text{or } Z_{10} &= k \sum_{\lambda=380}^{\lambda=780} I(\lambda) \bar{z}_{10}(\lambda) \end{aligned} \quad [3]$$

$L^*a^*b^*$ Colour Space (1976)

CIE $L^*a^*b^*$ colour space is based on the opponent theory of colour vision, which arose from the ideas of Hering. Hering pointed out that of the thousands of words used to describe hue, only four are unique; red, green, yellow and blue. They are unique because they cannot be described without using their own colour name, yet any other hue can be described using one or more words from this set. When taken together with white and black, they form a group of six basic colour properties that can be grouped into three opponent pairs, white/black, red/green and yellow/blue. The concept of opponency arises from the observation that no colour could be described as having attributes of both redness and greenness, or of both yellowness and blueness. A red shade of green just does not exist.

It seems sensible to associate these three opponent pairs with the three axes of a three-dimensional colour space. On a colour chart, the amount of redness or greenness of a colour sensation could be represented by the distance along a single axis, with pure red lying at one extremity and pure green lying at the other. In a similar way yellow and blue are opposite extremities of a second axis that could be placed perpendicular to the red/green direction. The third axis would go from white to black and lie in the plane normal to the other two. CIE

Figure 5 CIE $L^*a^*b^*$ colour space.

$L^*a^*b^*$ (1976) space uses three terms L^* , a^* and b^* to represent colour, as shown in **Figure 5** and described as follows:

- L^* The vertical axis represents lightness; 100 represents a perfect white sample and 0 a perfect black.
- a^* The axis in the plane normal to L^* represents the redness–greenness quality of the colour. Positive values denote redness and negative values denote greenness.
- b^* The axis normal to both L^* and a^* represents the yellowness–blueness quality of the colour. Positive values denote yellowness and negative values denote blueness.

$L^*a^*b^*$ values are calculated from XYZ values using the following equations:

$$F_X = \left(\frac{X}{X_0}\right)^{1/3} \quad [4a]$$

unless

$$\left(\frac{X}{X_0}\right) \leq 0.008856$$

when

$$F_X = 7.787 \left(\frac{X}{X_0}\right) + \frac{16}{116} \quad [4b]$$

where X_0 is the X tristimulus value of a perfect white sample under the chosen illuminant. Values of F_Y and F_Z are calculated in a similar manner. Then:

$$\begin{aligned} L^* &= 116F_Y - 16 \\ a^* &= 500[F_X - F_Y] \\ b^* &= 200[F_Y - F_Z] \end{aligned} \quad [5]$$

Since $L^*a^*b^*$ values for a sample may change for a different illuminant and observer combination, any colour specification must always include the illuminant and observer for which the values were calculated.

CIE $L^*C^*h^\circ$ Coordinates

The coordinates of the points representing the colour of a sample can also be expressed in cylindrical coordinates of lightness L^* , chroma C^* and hue b° , as illustrated in **Figure 6**. This system corresponds more closely to the natural description of colour.

L^* Lightness (see the preceding text)
 C^* Chroma:

$$C^* = \sqrt{a^{*2} + b^{*2}}$$

b° Hue angle:

$$b^\circ = \tan^{-1} \left(\frac{b^*}{a^*} \right) \quad [6]$$

Neutral grey samples would have C^* values between 0 and approximately 5 units. The hue angle is always measured anticlockwise from the positive a^* axis. It is traditional to associate one of the psychological primary hues with each axis direction, as shown in the diagram, although in reality the angles of the pure hues do not lie exactly along the axis directions.

Colour Difference

As the CIE $L^*a^*b^*$ system was designed to be visually uniform, it is fairly simple to devise an equation for the total colour difference between a trial and standard sample. The total colour difference is the distance

Figure 6 CIE $L^*C^*h^\circ$ colour coordinates.

between the two points representing those colours in the colour space, as shown in **Figure 7**. The distance, expressed as ΔE_{ab}^* , is determined using the laws of right-angle triangles:

$$\Delta E_{ab}^* = \sqrt{\Delta L^{*2} + \Delta a^{*2} + \Delta b^{*2}} \quad [7]$$

where

$$\Delta L^* = L_{\text{trl}}^* - L_{\text{std}}^*$$

$$\Delta a^* = a_{\text{trl}}^* - a_{\text{std}}^*$$

$$\Delta b^* = b_{\text{trl}}^* - b_{\text{std}}^* \quad [8]$$

The overall colour difference may also be split into lightness, chroma and hue terms, which again correspond more closely to the natural description of colour:

$$\Delta C^* = C_{\text{trl}}^* - C_{\text{std}}^* \quad [9]$$

$$\Delta H^* = \sqrt{\Delta E_{ab}^{*2} - \Delta L^{*2} - \Delta C^{*2}} \quad [10]$$

It is worth remembering that the scaling of the colour space was set so that a value of $\Delta E_{ab}^* = 1$ between the colour of two samples should be just visually perceptible. This means that if a large number of people were asked to judge the colour difference between the two samples, approximately 50% of observers would say that there was a difference in colour, the other 50% would say the two colours matched. This is the point of maximum argument.

Comparisons between the majority visual decision and a numerical assessment, based on the condition that

Figure 7 The CIE $L^*a^*b^*$ colour difference calculation.

ΔE_{ab}^* must be less than 1 for a match, show that the instrument decision will disagree with the majority visual decision approximately 19% of the time. On average, an individual colourist will disagree with the majority decision approximately 17% of the time when judging pairs of panels with fairly small colour differences. Pass/fail decisions based on the CIE $L^*a^*b^*$ (1976) equation with a limit of $\Delta E_{ab}^* = 1$ are, on average, slightly less reliable than visual judgements made by a single colourist. However, a colour-measuring instrument has the great advantage of giving much more repeatable decisions.

A number of scientists have devised more reliable or optimized colour difference equations. The simplest method of improvement is to assign individual tolerances to ΔL^* , Δa^* and Δb^* . Alternatively, individual tolerances can be assigned to ΔL^* , ΔC^* and ΔH^* (differences in lightness, chroma and hue). The most successful equations are based on the ΔL^* , ΔC^* , ΔH^* system of colour splitting and the CMC (l, c) and CIE 94 equations are of this type. The CMC equation was developed by the Colour Measurement Committee of the Society of Dyers and Colourists (Bradford, UK) and has been adopted as the ISO standard for small colour difference assessment of textile materials. In 1994 the CIE suggested the simpler CIE 94 equation for evaluation. The published evidence collected so far by the CIE suggests that pass/fail decisions made using either of the optimized colour difference equations are considerably more reliable than those based on ΔE_{ab}^* or on the judgement of a single human colourist. Comparison with decisions made by panels of observers show that the equations disagree with the majority decision approximately 13% of the time.

Colour and Appearance

The systems of colorimetry described earlier can only specify the colour of an isolated sample viewed against a neutral grey background. However, almost all colours are viewed against different backgrounds, with different fields of view, viewing environments, and states of adaptation to that environment. The surrounding colours or patterns will affect the perceived colour of the sample in ways which cannot be predicted using the CIE $L^*a^*b^*$ system. More complicated models have been developed that take these factors into account and the CIE have

recommended the CIECAM97s model for further testing. Colour appearance models are becoming increasingly important in these days of digital images and global communication. The faithful reproduction of an image from computer screen to printed hard copy requires an effective colour appearance model at the heart of the colour management system.

Summary

The use of colour-measuring instruments allows specification and communication of colour by means of international standard terms such as CIE $L^*a^*b^*C^*h^\circ$. Colour difference values can also be determined instrumentally and, if optimized colour difference equations are used, can out-perform a single trained colourist. However, the visual appreciation of colour and colour difference is still a subjective response, affected by many factors. Care must be taken to include measurement conditions in the interpretation of colour measurement data. The gold standard answer must always be that which agrees with the majority of a group of human observers. Whether this can be achieved by optimized equations based on CIE $L^*a^*b^*$ colour space or by colour appearance models remains to be established.

Introduction

In near-infrared and related spectroscopic methods, spectra consisting of spectroscopic measures (absorbance, transmittance, reflectance) at a large number of wavelengths, frequencies, energies or wavenumbers (also called by the general term ‘variables’) are produced. A few hundred to a few thousand variables are not uncommon, even with fairly simple, medium-priced instruments. For most uses it is not the study of the spectra itself (spectroscopy) but extracting information about the samples that is important. This requires a multivariate treatment. Some of the multivariate techniques used for this are presented here. Much of the explanation in this text will be based on figures showing spectra or plots visualizing analysis parameters and results. Since space is limited, equations are avoided in most instances and the reader is referred to the Further Reading section. Some lesser used multivariate techniques will be given just as literature references. Literature on the near-infrared technique and the related infrared, Raman and Fourier transform techniques is easily found in this Encyclopedia.

Raw Spectra

Near-infrared (NIR) spectroscopy is the study of spectra recorded on instruments in the region 780–2500 nm. Many instruments add the visual region of 400–780 nm to this, so that colour information in the spectra can also be studied. Other instruments are more restrictive, e.g. between 850 and 1050 nm. Technical details about instrumentation can be found elsewhere.

It is important to obtain a visual impression of the measured spectra and this is done in line plots. In these plots the horizontal axis is wavelength or wavenumber and the vertical axis can be transmission, reflectance or some type of calculated absorbance. Sometimes it may be useful to study a scatter plot of two raw spectra. Many researchers and industries prefer to work with transformed spectra and smoothing and derivation are used for that purpose (see **Figure 1**). Although raw spectra can show a great deal about classes of samples and outliers, some of the finer details cannot be found in them. Therefore, a more thorough, often multivariate analysis is needed. **Figure 2** shows a typical data matrix obtained from NIR measurement. Some instruments only use 19 well-selected wavelength bands and filters to give only 19 (or even fewer) variables. At the other extreme, some instruments give several thousands of wavelength variables.

Exploration and Classification

The first multivariate operation to be done on a data matrix (see **Figure 2**) is exploration of the data. Exploration of multivariate space is done by factor analysis methods, of which principal component analysis (PCA) is the easiest choice. The data are projected to a matrix with less and more meaningful variables called scores (latent variables) (see **Figure 3**). In **Figure 4**, a more complete view of PCA is given. Scatter plots of the scores are called score plots. Score plots are 2D windows in multivariate space. The points in the plots are the objects. In this way, outliers may be detected and groupings of objects may be found. The loadings explain how the original variables contribute to the scores. They can be used to study spectral properties, or

Figure 1 (a) A typical NIR spectrum and its (b) first and (c) second derivatives. The raw spectrum is in absorbance units.

to select wavelengths. Loadings are usually shown as line plots of one loading vector or as scatter plots of two loading vectors.

Any analysis of NIR data should start with the detection of outliers in score plots. The outliers should be identified and removed. After this, grouping of objects may be observed. Distinct groups, overlapping groups and gradients between groups may be found. Grouping may be supervised, meaning known in advance, or it may be unsupervised, i.e. found only after the analysis.

Figure 2 A typical data matrix from an NIR study. The number of objects I may be a few tens to a few hundreds; K may be a few tens to several thousands.

Figure 3 Principal component analysis (PCA) projects the K variables into A principal component scores containing all meaningful information about the samples.

Figure 4 PCA produces a score matrix and a loading matrix for A components and a residual matrix containing mainly noise. This is a data reduction.

With supervised grouping, one uses the score plot to check whether the expected (*a priori* known) groups really occur in the NIR spectra. Two different types of coffee are expected to have different spectra and if no difference can be found, the spectroscopic technique chosen may not be appropriate. Unsupervised grouping may show storage or sample treatment differences. A single type of coffee may give grouped spectra because different storage conditions have resulted in different humidity or because the grinding was performed in different machines.

Studies of score plots may be used for studying grouping, ageing, deterioration, erroneous processing or counterfeiting of all kinds of organic products, e.g. food and feed products, cellulose, paper and textiles, wood products, fossil fuels and biofuels, seeds and growing crops, pharmaceuticals, packaging materials and environmental samples. An industrial application is to keep the spectra of satisfactory batches or products in a file and to compare new spectra to see if they still fit the 'satisfactory' group. A large collection of classification methods (sometimes called 'pattern recognition') is found in the literature, but many of these methods are less useful for NIR data because of the huge number of variables compared with objects. Also in this respect, a data reduction to scores is

useful, allowing the use of the classical clustering and pattern recognition techniques on a limited number of score vectors. Statistical tests can be applied to the residual matrix.

Calibration

One of the main purposes of measuring NIR data is the determination of chemical composition or physical properties in a quantitative way. It was found very early that NIR spectra contain information on the water, protein, carbohydrate and fat content of food products. Measuring an NIR spectrum is quick and cheap (30–60 samples per hour for solids) while the wet chemical methods for measuring water, fat, protein, and carbohydrates are slow and expensive. Hence if a function $y=f(x)$ can be found where x is the NIR spectrum and y is the desired chemical concentration, then time and money are saved. As an extra advantage, the NIR spectral measurement can be automated to function continuously on a process stream. Constructing and testing the functions $y=f(x)$ is calibration. Using the function $f(\cdot)$ to find a value of y with only x known is prediction. Many methods are available for finding $f(\cdot)$ and many diagnostics are available for checking its quality. Generally, for the calibration step, accurate and precise measures of y and x are required. However, noise can never be avoided. Therefore, it is impossible to find an exact function $f(\cdot)$ and approximations have to be found. Linear approximations are easy to calculate, more easily interpreted and robust. Therefore, a linear model $y=xb+f$ is often adequate. One important aspect to point out is that in the equation $y=xb+f$ both x (the spectra) and y (the response) have systematic and random noise.

There are many different techniques for building transfer functions between spectra and quantities (responses) measured by a reference method. Several techniques are found in the literature, but not all of them are frequently applied. The equation given above can be extended to $y=Xb+f$ or even to $Y=XB+F$ (see Figure 5), with y ($I \times 1$) a vector of response values for many samples, Y ($I \times M$) a matrix of response values for many responses, X ($I \times K$) the spectral data for the samples, b ($K \times 1$) a vector of regression coefficients, B ($K \times M$) a matrix of regression coefficients for the M responses, f ($I \times 1$) a vector of residuals and F ($I \times M$) a vector of residuals for many responses. One may consider percentages of fat, water and protein as three different responses ($M=3$). The traditional least-squares solution for b (B) is called multiple linear regression or ordinary least squares. The method was used in the pioneering days of NIR, when there were only few wavelength bands available.

Figure 5 A regression model is built between the matrix X with NIR spectra and the responses Y . The regression coefficients B have to be calculated by MLR, SMLR, PCR, PLS, RR, ANN, etc. F is the residual containing the noise.

The selected linear regression methods differ in the way the regression coefficients are estimated. They also have different properties for outlier detection and other diagnostics. In the early days it was found that wavelengths produced by spectrophotometers caused problems in a regression situation because of collinearity between the variables. There is also the problem of finding a least-squares solution to the equation above when the number of samples is less than the number of variables. Some selected methods are outlined below.

Stepwise Multiple Linear Regressions (SMLR)

SMLR is a way of cleverly reducing the number of wavelengths in order to find a least-squares solution, based on the meaningful assumption that repeated and useless information may be present in some wavelengths. In stepwise multiple linear regression, one starts with selecting the wavelength amongst all available ones that correlates the best to the measured response. When the first wavelength is found, another wavelength is selected that increases the degree of explanation maximally and so on, until a stop criterion is fulfilled.

Principal Component Regression (PCR)

PCR uses the scores from a principal component analysis to avoid the problems of many variables and collinear variables described earlier. The PCA part also gets rid of some of the noise in the spectral data as an extra advantage. The regression solution becomes easier to calculate and more stable, and one obtains predictions that are more reliable. In addition, the PCA scores give the possibility of outlier detection, both for samples in the calibration data and for later samples for prediction.

Partial Least-Squares Regression (PLS)

PLS is similar to PCR, in that regression is done on scores. The difference is that the responses y (Y) are used to find scores that have a large covariance between X and y (Y). One advantage of PLS over PCR is that the number of required components is reduced. Since PLS is used on scores, these can be used for the detection of outliers and groupings, as was explained for PCA. In this way, PLS automatically gives access to a number of diagnostic tools for outlier detection (in X and y). PCR and PLS add an important parameter to the regression model: the number of components used in the model, A . This is an extra choice to be made. Too few components give a bad model and too many components give a model that is sensitive to noise. PLS, PCR and MLR variants are the most commonly used regression methods for quantification of multivariate spectral data. Other methods are ridge regression (RR) and continuum regression (CR).

Artificial Neural Networks (ANNs)

The use of ANNs is increasing. ANNs are especially used for pattern recognition and nonlinear calibration. There are many types of ANN. However, it seems that the back-propagation ANNs are the most useful for calibration purposes. In linear calibrations, the traditional linear regression techniques will more often give stable and robust results as compared with ANNs. However, in nonlinear situations and with large heterogeneous data sets, ANNs work very well.

Locally Weighted Regression (LWR)

LWR is based on the idea that even in a nonlinear situation there exist regions where a local model is close to linear. In LWR the neighbours of a spectrum to be used for prediction are used to build a local regression model. This model can be determined by PCR or PLS. There are different techniques for selecting appropriate neighbours, using different distance criteria and weighting (see **Figure 6**).

In addition to the building of regression models, testing them is also important. Therefore, the data are split into a training set (size I) on which the model is built and a test set (size J) that is used for testing the model in a simulated 'real' situation (see **Figure 7**). Checking how well this works is called validation and is explained in its own section below. Calibration is very important for NIR data since the classical interpretation of the spectra (as is done for IR and UV spectra) is nearly impossible. Because of this, one may state that there is a very close relationship between an NIR instrument and the calibration model, making an instrument useless if no calibration model is available. A complete flow chart for NIR data analysis is given in **Figure 8**.

Figure 6 Nonlinear relationship between the variables x and y . However, when the range is narrowed, local linear models can be used.

Figure 7 The training set (I objects) is used to find the regression coefficients vector b . With a test set (J objects), the predicted responses can be calculated using the same b . Usually the responses for the test set are kept in the background for diagnostic checking.

Validation

It is very important to test the quality of a regression model constructed by PCR, PLS or any other regression method. The model for the training set (see **Figure 7**) can be improved by using more PCR or PLS components, but some of these will only describe noise. With

Figure 8 A flow chart for a complete NIR data analysis.

Figure 9 A plot of RMSEP against the number of components used in the model gives a minimum (arrow) indicating how many components should be in the model and how low the prediction error can be made.

an appropriate test set, a check can be made whether the model also has predictive properties. A revealing test is to plot the predicted values for the test set against the measured values in a scatter plot. In this plot, all points should ideally fall on the diagonal. Outliers, systematic errors, groupings and noisy behaviour are all detected easily. Sometimes numbers are needed. The predicted responses $\hat{y}$ for the test set can be compared with the measured values y_t . This is done by constructing a sum of squares $\text{PRESS} = (y_t - \hat{y})(y_t - \hat{y})$ and the corresponding standard deviation $\text{RMSEP} = [\text{PRESS}/J]^{1/2}$. A useful plot is that of PRESS (prediction residual sum of squares) or RMSEP (root mean square error of prediction) against the number of components in the model (see **Figure 9**). When I and J are very small because of lack of samples, cross validation may be used advantageously. **Figure 10** shows a typical predicted versus observed plot.

Calibration Transfer

The building of a good, robust calibration model with excellent prediction properties is extremely important and sometimes very expensive and time consuming. In many uses of NIR instruments and calibration models, long series of measurements are required and one has to be sure that the calibration model works well over long periods of time. This is not easy since instrument ageing, parts replacement and repairs may create the need for a new calibration model. Another situation arises when different instruments are used to do the same task in parallel. In order to avoid repeating the calibration, the techniques of calibration transfer have been developed. Some calibration transfer techniques are based on keeping individual instrument differences small or compensating in the instrument hardware itself. Others work by calculations for making the spectra from

Figure 10 Plotting predicted values of the response against observed values gives an idea of prediction quality. All points should fall close to the diagonal. Individual outliers or deviating groups can easily be detected.

one instrument (the field instrument) look like those of another one (the master instrument). In this way, the calibration model from the master instrument can still be used successfully.

Pretreatment of the Spectra

Several pretreatments are used in the processing of spectral data. The usual mean centring, scaling and nonlinear transformations are part of normal procedure related to classification and regression. Some other techniques were developed specifically with the nature of the NIR measurement in mind. The main purpose is always to improve the performance of a classification or calibration. Pretreatments can also be used to compress spectral information and ease computation on large sets of data, as is the case with Fourier and wavelet transforms. Multiplicative signal correction (MSC) was originally developed for NIR reflectance data in order to correct for different pathlengths and scatter arising from different particle sizes in the samples. This is done by adjusting baselines and slopes. The basis for MSC is simple.

Each spectrum is compared with a reference spectrum, usually the mean spectrum of all good calibration samples. The sample spectrum is assigned the same offset and average slope as the reference spectrum. Orthogonal signal correction (OSC) works in a similar way to MSC but uses the responses for orthogonalization, thus ensuring that all information related to the responses stays in the transformed spectra. Derivatives (see **Figure 1**) encompass basically the same thing as MSC. A second derivative of a spectrum removes baseline offsets and linear slopes. Derivation (or differentiation) is a widely used, simple and intuitive data pretreatment. For digitized spectra, different smoothing algorithms can also be applied, e.g. using different widths of derivation.

Symbols

A_m	abundance at mass m (weighted peak intensity)
b	parameter of discriminant function
d	distance
I_m	intensity (peak height) at mass m in %base peak
m	mass number
n	number of compounds or spectra
p	probability
q	number of variables (masses, spectral features)
R	reference spectrum
S	similarity between two mass spectra
U	spectrum from unknown
x	spectral feature
z	discriminant variable

Mass spectra of chemical compounds have a high information content. This article describes computer-assisted methods for extracting information about chemical structures from low-resolution mass spectra. Comparison of the measured spectrum with the spectra of a database (library search) is the most used approach for the identification of unknowns. Different similarity criteria of mass spectra as well as strategies for the evaluation of hitlists are discussed. Mass spectra interpretation based on characteristic peaks (key ions) is critically reported. The method of mass spectra classification (recognition of substructures) has interesting capabilities for a systematic structure elucidation. This article is restricted to electron impact mass spectra of organic compounds and focuses on methods rather than on currently available software products or databases. This article covers methods and applications that were current in the mid-1990s. However, a short update describing some more recent developments together with some literature sources has been included at the end of this article.

Introduction

Mass spectrometry (MS) is the most widely used method for the identification of organic compounds in complex

mixtures at the nanogram level and below. NMR and, sometimes, also infrared spectroscopy can often provide better structural information than MS data, and these spectroscopic methods can now be coupled with chromatographic separation techniques. Despite the great amount of information contained in mass spectra it is difficult to extract structural data because of the complicated relationships between MS data and chemical structures. The fragmentation processes which finally result in the measured data characterize MS as a chemical method, in contrast with NMR and IR. Chemical effects are, in general, more difficult to describe and to predict than physical ones. The occurrence of rearrangement reactions means that structure identification from mass spectra is often difficult or impossible; furthermore, functional groups do not always produce the same peaks. Structure elucidation in organic chemistry is mainly based on a combination of ^{13}C NMR ^1H NMR, IR, UV–VIS and MS data.

The aim of spectra evaluation can be either the identification of a compound (assuming the spectrum is already known and available) or interpretation of spectral data in terms of the unknown chemical structure (when the spectrum of the unknown is not available).

Identification is performed best by library search methods based on spectral similarities; a number of MS databases and software products are offered for this purpose and are routinely used.

The more challenging problem is the interpretation of a mass spectrum, which is still a topic of research projects in chemometrics and computer chemistry. Four groups of different strategies have been applied to the complex problem of substructure recognition (or the recognition of more general structural properties) from spectral data. (1) *Knowledge-based methods* try to implement spectroscopic knowledge about spectra–structure relationships into computer programs. Because of the lack of generally applicable rules, this approach was not successful in MS. However, spectroscopic knowledge has been extensively applied in other methods to guide the construction of mathematical models and to optimize/model parameters. (2) Appropriate *interpretive library search* techniques can be used to obtain structural information if the unknown is not contained in the library. (3) *Correlation tables*

containing characteristic spectral data (key ions) together with corresponding substructures have met with only limited success because a specific structural property does not always give the same spectral signals. (4) *Spectral classifiers* are algorithms based on multivariate classification methods or neural networks. They are constructed for an automatic recognition of structural properties from spectral data.

In principle, mass spectral data are fully determined by the chemical structure of the investigated compound and the experimental spectroscopic conditions

$$\text{mass spectral data} = F(\text{chemical structure,} \\ \text{experimental spectroscopic conditions})$$

For problems of practical interest, however, the relationship F can neither be formulated as a mathematical equation nor as an algorithm. Consequently, methods for the prediction of the mass spectrum from the chemical structure have had only very limited success. A similar difficult situation arises for the inverse problem, spectra interpretation, **Figure 1**. Only for selected cases can the relationship

$$\text{structural property} = f(\text{selected mass spectral data})$$

be established and applied to mass spectra of unknowns. Some relationships f for different structural properties have been developed by the use of statistical methods or neural networks rather than by the influence of spectroscopic knowledge.

Because of these difficulties, the intervention of the human expert is still required in mass spectra interpretation. However, this situation causes a number of drawbacks. Human experts are not sufficiently available and are expensive; furthermore their success rate can hardly be quantified. Automated instruments with high throughput are able to produce huge amounts of data, and analytical interest in complex mixtures (environmental chemistry, food chemistry, biofluids and other biochemical mixtures, combinatorial synthesis) is rapidly

increasing. Thus the extensive use of computer-assisted methods for data interpretation is highly desired.

Characteristic Mass Spectra Signals

A number of masses in the low-mass region (*key ions*) are considered to be characteristic for certain substructures or classes of compounds. In addition, mass differences (*key differences*) between the molecular ion and abundant fragment ions or between abundant fragment ions are often related to functional groups. Correlation tables containing such spectral data and the corresponding chemical structures are contained in several textbooks on MS. The use of these tables is widespread and often helpful in MS; however, the capability of this approach must not be overestimated.

The following example demonstrates the potentials and drawbacks. From the NIST Mass Spectral Library, a random sample containing 5000 compounds with a phenyl group (class 1) and 5000 compounds without a phenyl group (class 2) have been selected. From these data it was estimated whether the signal at m/z 77 (corresponding to the ion C_6H_5^+) can be used to predict the presence or absence of a phenyl group in the molecule. Let n_1 be the number of compounds from class 1 exhibiting a peak at m/z 77 in a given intensity interval, and n_2 be the corresponding number for compounds from class 2. Assuming for an unknown compound that the a priori probability for belonging to class 1 is 0.5, the probability $p(\text{phenyl} | I_{77})$ can be calculated from the signal at m/z 77 as

$$p(\text{phenyl} | I_{77}) = \frac{n_1}{(n_1 + n_2)} \quad [1]$$

Table 1 shows results for this example using four intensity intervals. Depending on the intensity of the peak at m/z 77, the probability for the presence of a

Figure 1 Relationships between mass spectrum and chemical structure.

phenyl group decreases or increases. If a peak at m/z 77 is absent or has an intensity not higher than 1% of the base peak (%B), the probability for the presence of a phenyl group is still 17%. Intensities above 60%B strongly indicate a phenyl group (91% correct assignments to class 1). However, most spectra have peak intensities between these limits and therefore do not allow a reliable answer about the presence or absence of a phenyl group. A systematic examination of approximately 40 key ions between m/z 30 and 105 can be summarized as follows: (1) only a small number of key ions provide significant structural information and (2) the absence of a key ion in general does not indicate the absence of the corresponding compound class.

Table 1 Significance of a peak at m/z 77 for the presence of a phenyl group in a molecule

Intensity interval (%B)	n_1	n_2	$p(\text{phenyl} I_{77})$
$I \leq 1$	497	2486	0.17
$1 < I \leq 5$	738	983	0.43
$5 < I \leq 30$	2283	1288	0.64
$30 < I \leq 60$	898	182	0.83
$60 < I$	584	61	0.91
Sum	5000	5000	

The terms n_1 and n_2 are the number of spectra (compounds) with a peak at m/z 77 in the given intensity interval for compounds that contain a phenyl group and those that do not, respectively; $p(\text{phenyl} | I_{77})$ is the a posteriori probability for the presence of a phenyl group (assuming an a priori probability of 0.5).

Mass Spectra Similarity Search

Overview

A basic assumption in library search systems is the hypothesis that 'similar spectra often correspond to similar structures'. A search for spectra in a library can be guided by two types of criteria: (1) a search profile is defined by some logical restrictions, for example 'peak height at m/z 77 > 90%B and peak height at m/z 105 > 30%B'. The result is a not-ordered hitlist containing all spectra that exactly match the search profile. (2) A numerical similarity between two spectra is used to find the reference spectra most similar to the spectrum of the unknown (**Figure 2**). In this case the resulting hitlist is ordered according to the value of the similarity criterion. Of course any type of search can be combined with additional search criteria (relative molecular mass range, restrictions to the molecular formula, name fragments, etc.). Unfortunately, the capabilities for chemical structure searches are still very limited in commercially available MS databases.

The performance and effectiveness of a spectral library search depends on the quality of the given spectrum, the content of the spectral library, the used similarity criterion and the implemented software technique. A fundamental restriction is given by the limited structural information present in mass spectra, for instance, isomers can often not be distinguished by their mass spectra.

Libraries

Any spectroscopic retrieval system in chemistry depends on an appropriate structural diversity of the reference

Figure 2 Spectral library search.

Table 2 Common quality problems with mass spectra in databases

Spectrum reduced to a small number of (large) peaks
Limited mass range (start mass too high)
Peaks present far above the relative molecular mass
Poor dynamics of peak intensities
Wrong isotope peak intensities
Tilted peak intensities
Additional peaks from impurities or instrument background
Small peaks missing
Wrong mass assignment
Illogical mass differences
Spectrum does not match with given compound
Missing experimental data
Missing structure data
Too many replicate spectra

data. Commercially available MS databases today contain approximately 40 000 up to almost 300 000 spectra. Some libraries contain a number of replicate spectra (collected from different sources), especially for common compounds. The compositions of existing libraries (except a few dedicated small spectra collections) are not systematic. Some compound classes are very well represented (for instance hydrocarbons) while others are not but may be of major interest to a particular user. Good software support for building user libraries is therefore essential. **Table 2** lists common problems of quality deficiencies in MS reference data.

Peak Search

A simple and evident method for library search of mass spectra applies user-selected restrictions for the presence of peaks. Initially, a characteristic peak in the spectrum of the unknown is selected (typically one at a high or unusual mass number and with a not too small intensity) and an intensity interval for reference spectra is defined. The peak search software answers with the number of reference spectra containing a peak at the given mass and in the given intensity interval. This procedure is continued until a reasonable number of hits is reached (in cases where no reference spectrum fulfills all restrictions it is possible to go back one step). The resulting list of spectra can be ordered by applying an additional similarity criterion. The method allows (and requires) the interaction of the user; consequently spectroscopic knowledge (for instance about the background peaks) can be easily considered; however, automated processing of spectra is not possible. The use of appropriate sorted index files avoids time-consuming sequential searches and makes the method very fast. An example for this method is presented in **Figure 3**.

Spectra Similarity Criteria

An infinite number of different similarity measures for matching two mass spectra is possible. In reality, about a

Figure 3 Peak search example using the NIST mass spectral database. The mass spectrum of a hypothetical unknown is from caffeine contaminated with a phthalate. Manual selection of relevant peaks easily allows the spectroscopist to consider probable contaminations (peaks at m/z 149, 167). The correct solution is found after the input of four peaks by excluding the typical phthalate peaks. Note the wide intensity intervals applied. If the peak at 149 had been used, the correct compound would not have been found.

dozen similarity criteria have been described and tested; however, full details of the algorithms that are actually implemented in commercial software are seldom described. Some similarity criteria are purely mathematically oriented, others are influenced by spectroscopic ideas. A single criterion cannot fit all requirements: on the one hand, a compound which is contained in the library should be retrieved even if the spectrum deviates in some parts from the reference spectrum; on the other hand, the user expects hits with chemical structures similar to the unknown even though they exhibit different spectra. In the ideal case, the similarity criterion has a practicable sensitivity to chemical structures: identical compounds measured under different spectroscopic conditions appear more similar than two compounds that are slightly different in their structure.

The two main types of mass spectral data, peak heights and masses have different reliability. While the presence of a peak at a certain mass number is well reproducible, the peak height often varies greatly under slightly different experimental conditions. Spectra similarity criteria have to consider this aspect.

For similarity searches, an efficient ordering of the spectra in the library is not possible and, therefore, a rather time-consuming sequential search is necessary. Some speed-up is possible by a pre-search in which, for instance, reference spectra are quickly eliminated that do not have a minimum number of peaks in common with the spectrum of the unknown. Before calculating the spectra similarity the spectrum of the unknown is treated

by cleaning procedures, for instance peaks at m/z 28, 32 and 40 (probably from N_2 , O_2 and Ar, respectively) and peaks from column bleeding are removed, and the peak heights are normalized to percents of the base peak. The selection of relevant peaks and weighting of peak heights is described in articles in the Further Reading. Let ${}_U A_m$ and ${}_R A_m$ be the (weighted) abundances at mass m in the spectrum of the unknown (U) and the reference spectrum (R), respectively. Summation in eqns [2]–[4] is over all selected masses m .

The most used similarity criterion for mass spectra is based on the *correlation coefficient*

$$S_1 = \frac{[\sum {}_U A_m {}_R A_m]^2}{\sum [({}_U A_m)^2 \sum ({}_R A_m)^2]} \quad [2]$$

Figure 4 explains this similarity criterion: each mass is considered as a point in a coordinate system with one axis for the abundances of the unknown and the other for the reference. For identical spectra, all points are located on a straight line that passes through the origin ($S_1 = 1$). If the two spectra are different, the correlation coefficient for the regression line – as given in eqn [2] – is a measure of the similarity of the spectra. The value of S_1 ranges from 0 to 1 because the regression line is forced to pass through the origin and all abundances are 0 or positive. The important range of S_1 between 0.9 and 1 can be widened by calculating S_1^2 ; for practical reasons S_1 or S_1^2 are often multiplied by 100.

A peak list with nominal (integer) masses can be considered as a point in a q -dimensional space, with q equal to the maximum relevant mass number. The coordinates of the point are given by the abundances (weighted peak heights). Because the value of q is high, the q -dimensional space cannot be visualized directly but can be handled by rather simple mathematics. A two-dimensional simplification is used in Figure 5 to demonstrate this view of MS data. Masses 43 and 58 have been selected for the coordinates; each spectrum (from the example in Figure 4) can be represented by a point or by a vector (starting at the origin). Similarity criterion S_1 is equal to the cosine of the angle between two spectral vectors.

Alternative similarity measures are the *Euclidean distance* S_2

$$S_2 = \sqrt{[\sum ({}_U A_m - {}_R A_m)^2]} \quad [3]$$

and the *city block distance* S_3

$$S_3 = \sum |{}_U A_m - {}_R A_m| \quad [4]$$

The similarity criterion used in the PBM (Probability-Based Matching) software is based on so-called uniqueness values for masses and abundances. The uniqueness of a signal is equivalent to the information content (as defined in information theory) and is given by the negative

logarithm of the probability of the occurrence of this signal; this means that a low probability corresponds to a high uniqueness. Probabilities for masses and intensity intervals have been estimated from the database used. Matching of spectra is performed by using selected peaks that exhibit highest uniqueness values for mass and intensity.

The MS database system MassLib uses a composite similarity criterion containing the similarity criterion S_1 together with measures for the number and intensity sums of peaks that are common or not in both spectra. The algorithm has been optimized to give good results for identification as well as for interpretation.

In the STIRS (Self-training Interpretive and Retrieval System) for 26 data classes, specific similarity criteria are defined using characteristic masses or mass differences. For each of these criteria, the most similar reference spectra are searched with the aim of obtaining information about the presence of substructures.

Weighting

Intensity scaling and mass weighting is used to consider the different significances of mass numbers and peak heights. In general, peaks in the higher mass range are more important than peaks in the lower mass range; because large peaks dominate the values of most similarity criteria, peak heights are often scaled to enhance the influence of small peaks. A general transformation of intensities I_m at mass m is given by eqn [5]

$$A_m = (m)^v (I_m)^w \quad [5]$$

Optimum values for v and w depend on the used similarity criterion; for S_1 (eqn [1]) good results have been obtained with $v=2$ and $w=0.5$ (see Stein and Scott (1994) in the section 'Further Reading').

Selection of Relevant Masses

The selection of masses used to calculate a spectral similarity may greatly influence the result. The user often can decide between three modes for mass selection (Figure 6).

- All masses for which at least one of the compared spectra has a peak with an intensity above a defined threshold are considered. High similarity values are obtained only if the spectra are almost identical; this approach therefore is suited for *identity searches* (sometimes also called *purity searches*).
- Only masses with a peak in the reference spectrum are considered. High similarity values are obtained if the reference spectrum is almost completely contained in the spectrum of the unknown. Non-matching peaks in the unknown do not influence the

Figure 4 Comparison of the mass spectrum from an unknown with two reference spectra using the similarity measure S_1 (based on the correlation coefficient). Axes in the two plots at the bottom: horizontal, peak height %B of unknown; vertical, peak height %B of reference. Each point corresponds to a mass number with a peak in at least one of the two compared spectra.

result; therefore, this approach is routinely applied if the unknown may contain impurities or is a mixture of compounds (*fit search, reverse search*).

- (c) Only masses with a peak in the spectrum of the unknown are considered. This method is not tolerant of additional peaks in the reference spectrum. From a high similarity value one may conclude that parts of the

chemical structure of the reference compound are present in the unknown (*interpretive search, forward search*).

Simple selection methods of peaks such as ' k highest peaks in the spectrum (or in given mass intervals)' have been applied to save data storage and computation time but are no longer important. A special selection of masses

Figure 5 Mass spectra can be considered as points or vectors in a multidimensional spectral space. For simplicity only two mass numbers (43, 58) have been selected in this example. A_m , abundance (peak height in %B) at mass m ; U, spectrum from unknown; R1, reference spectrum of propanal; R2, reference spectrum of acetone. Measures for spectral similarity are the Euclidean distance (d), the city block distance ($\Delta_{43} + \Delta_{58}$) or the cosine of angle α (equivalent to S_1 in eqn [2]).

Figure 6 Different selection of masses for the calculation of spectral similarity (schematic). The fit search considers only masses with peaks in the reference spectrum and therefore is insensitive to impurities in the unknown.

is used in the MassLib system: a peak at mass m is considered to be significant if its intensity is higher than the average intensities at masses $m - 14$ and $m + 14$.

Figure 7 presents an example of an MS library search in which the unknown was contained in the library.

Mass spectra classification

Overview

When the unknown compound is not contained in the spectral library then pure identification methods are less useful. For 'unknown unknowns' interpretive search systems or classification methods are required to obtain structural information that can be used for constructing molecular structure candidates. Such candidates are usually created manually by applying spectroscopic-chemical

knowledge and intuition. A serious drawback of this strategy is that the solution is rarely complete and the procedure can hardly be documented or verified.

The most important systematic approach for structure elucidation of organic compounds is still based on the DENDRAL project, in which, for the first time, artificial intelligence principles have been applied to complex chemistry problems (Table 3). The central tool is an isomer generator software capable of generating an exhaustive set of isomers from a given molecular formula. The generator also has to consider structural restrictions which are usually obtained from spectral data. Substructures which have to be present in the unknown molecular structure are collected in the so-called good list, while forbidden substructures are put into the bad list. MS can contribute to this approach in various aspects: the molecular formula can be determined from high-resolution data, and structural information can be derived even from low-resolution data.

The two most important computer-assisted strategies for the recognition of structural information from mass spectral data are the following:

- The structures in the hitlist from a spectra similarity search are used to estimate the probability of substructures in the unknown.
- Random samples of mass spectra are first characterized by a set of variables and then methods from multivariate statistics or neural networks are applied to develop spectral classifiers.

Substructure Recognition by Library Search

Library search systems have been developed or adjusted for the purpose of obtaining structurally similar compounds in the hitlist. In such methods an evaluation of the molecular structures of the hitlist compounds can provide useful information about the presence or absence of certain substructures in the unknown.

It is not trivial to define or select substructures that should be considered for this purpose. For the STIRS system, considerable effort has gone into the search for substructures that can be successfully classified by the implemented spectral similarity search. The MassLib system uses a predefined set of 180 binary molecular descriptors to characterize the similarity of structures. In most investigations a more or less arbitrary set of substructures, functional groups or more general structural properties (compound classes) has been considered. Self-adapting methods that automatically analyse the molecular structures in the hitlist (for instance by searching for frequent and large substructures) have not been used up to now in MS.

The number of occurrences of a certain substructure in the hitlist is compared with the corresponding number

Figure 7 Example of a library search by MassLib. A mass spectrum from testosterone has been considered as unknown and searched in a library consisting of 130 000 spectra (including duplicates). A mass spectrum from testosterone is contained in this library and has been found as the first hit (most similar spectrum). The other hits are from the same compound class and demonstrate the interpretive capabilities of this system.

for the library and a probability is derived for the presence of that substructure in the unknown. This classification method is a variant of the well-known '*k*-nearest neighbour classification'. Each mass spectrum is considered as a point in a multidimensional space; the neighbours nearest to the spectrum of the unknown correspond to the most similar reference spectra in a library search. If the majority of *k* neighbours (*k* is typically between 1 and 10) contain a certain substructure then this substructure is predicted to be present in the unknown. A drawback of this approach is the high computational effort necessary for classifying an unknown because a full library search is required. The performance has been described by Stein and Scott (1994, see Further Reading section) as 'sufficient to recommend it for routine use as a first step in structure elucidation'.

Multivariate Classification

A *mass spectral classifier* is a part of a computer program that uses the peak list of a low-resolution mass spectrum as input and produces information about the chemical structure as output. For such a classification procedure a number of methods are available in multivariate statistics. Many of them have already been applied to various problems in chemistry; classification of mass spectra (with the aim of recognizing chemical compound classes) was one of the pioneering works in chemometrics.

Application of most multivariate classification methods first requires a transformation of the data to be classified (the mass spectrum) into a fixed number of variables (so-called features). Besides the simple use of the peak intensities for these variables more sophisticated transformations have been applied. Problem-relevant

Table 3 Scheme for systematic structure elucidation

- (1) Determine the molecular formula of the unknown
- (2) Derive structural restrictions as substructures from spectral and other experimental data and from pre-knowledge about the unknown
- (3) Make consistency checks of the structural restrictions
- (4) Add all substructures that are considered to be present in the unknown to the good list. Add all substructures that are considered to be absent in the unknown to the bad list
- (5) Generate all isomers for the given molecular formula that contain all substructures from the good list but none from the bad list
- (6) Test the generated molecular candidate structures:
 - (a) by a comparison of predicted spectra with measured spectra
 - (b) by a comparison of predicted properties with measured properties
 - (c) by considering more complicated structural restrictions that could not be handled by the isomer generator
- (7) If the number of survived molecular candidates is too large try to create additional structural restrictions and continue at step 3

numerical spectral features x_j are defined as linear or non-linear functions of the peak intensities; the definitions are based on spectroscopic and mathematical concepts. Table 4 contains a list of frequently used spectral features for mass spectra. It has been shown that such features are more closely related to chemical structures than the original peak data; an example will illustrate this. A characteristic fragment in a homologous series of compounds may not appear at the same mass but may be shifted by a multiple of 14 mass units, corresponding to $(\text{CH}_2)_n$. The often used modulo-14 summation features (also called mass periodicity spectra) consider this fact by an intensity summation in mass intervals of 14. Other spectral features are based on intensity ratios and reflect competing fragmentation pathways; autocorrelation features contain information about mass differences between abundant peaks. The stability of molecular ions and some functional groups can be characterized by features that describe the distribution of peaks across the mass range. The appropriate generation and selection of spectral features is considered to be the most essential part in the development of spectral classifiers.

The development of a classifier (Figure 8) for a particular substructure requires a random sample of spectra which is selected from a spectral library. Typically, some 100 spectra from compounds containing the substructure (class 1) and some 100 spectra from those not containing the substructure (class 2) are necessary. One part of the random sample is used for a training of the classifier, the other part for testing it. Classification is based on the value of a discriminant variable z which is defined either as a linear function of the q selected spectral features x_j

$$z = b_1x_1 + b_2x_2 + \dots + b_qx_q \quad [6]$$

Table 4 Types of numerical spectral features; a set of spectral features can be used to classify a mass spectrum as to whether a certain substructure or a more general structural property is present or absent in the molecule

Modulo-14 intensity sums	$x_j = \sum I_{m+14n}$	$n : 0, 1, 2, \dots, j,$ $m : 1, 2, \dots, 14$ $I_m = \max(I_m, 1)$
Logarithmic intensity ratios	$x_j = \ln I_m / I_{m+\Delta m}$	$j, \Delta m : 1, 2, \dots, 50$ $m : \text{a defined mass range}$
Autocorrelation	$x_j = \sum I_m I_{m+\Delta m} / \sum I_m^2$	$m : \text{all even masses}$ $m : \text{all masses}$
Distribution of peaks	$x_j = \sum I_{\text{even}} / \sum I_m$	$m : \text{all masses}$
Relative base peak intensity	$x_j = 100 / \sum I_m$	$m : \text{all masses}$

x_j , spectral feature; I_m , intensity in %base peak at mass m ; Δm , mass difference

**Figure 8** Classification scheme for mass spectra. The mass spectrum is transformed into a set of typically 5 to 20 variables (spectral features). A linear or non-linear mathematical combination of the features results in a discriminant variable. The value of the discriminant variable together with the required maximum statistical risk for wrong answers determines which of the three possible answers is given: 'class 1' (substructure present), 'class 2' (substructure absent) or 'answer not possible because error risk is too high'.

or as a non-linear function which is usually implemented as a neural network. During the training process, the parameters of the classifier can be directly calculated (as for instance by multiple linear regression or partial

least-squares regression) or they have to be adjusted iteratively (if a neural network is used). The aim of the training is to obtain values for z as defined by target values (for instance $+1$ for class 1 and -1 for class 2). The test set (which has not been used for the training) serves to estimate optimum classification thresholds z_1 and z_2 for applications of the classifier to unknowns by the scheme:

```
IF  $z < z_1$  THEN assign compound to class 1
IF  $z > z_2$  THEN assign compound to class 2 [7]
ELSE reject classification answer
```

Simple yes/no classifiers without the possibility to refuse the classification answer are not adequate for the recognition of substructures from mass spectra.

Today's performance of mass spectra classification by multivariate methods can be summarized as follows: (1) only a rather small number of substructures can be recognized with a low error rate. (2) Predictions of the absence of a substructure are usually more accurate than predictions of its presence. (3) Erroneous classifications cannot be avoided completely; therefore, the intervention of a human expert and the parallel use of other spectra interpretation methods are advisable. (4) For small molecules a systematic and almost complete structure elucidation is sometimes possible by mass spectra classification and by application of the obtained structural restrictions in automatic isomer generation.

An example for this approach of structure elucidation is presented in **Figure 9**, where ethyl 2-(2-hydroxyphenyl)acetate has been considered as unknown. The molecular formula and the mass spectrum are given. Application of the software classifier resulted in substructures that are assumed to be present (good list) and others that are assumed to be absent (bad list); only substructures relevant to the molecular formula are shown. Considering these structural restriction, six isomers are possible, including the correct solution. The isomer generator used was MOLGEN.

Updated Information

McLafferty et al. evaluated the quality of MS databases available in 1999. The high success of 'uncertified' mass spectrometry spectral collection that started in 1956 demonstrated qualitatively that a partial reference mass spectrum, even one measured routinely, can be of real value. Correct matchings were still possible despite reference errors, which almost never led to close matches that were incorrect. This study showed quantitatively that the number of different compounds, not the number of peaks in a spectrum, is by far the most important determinant of database efficiency for identifying a

'global' unknown. A statistical evaluation of matching performance showed that only 6, 12, and 18 peaks in a reference spectrum are 13%, 67%, and 96%, respectively, as valuable as hundreds of peaks. Also, a separately measured second spectrum of the same compound is 50% as valuable as the first. Database expansion that tripled the number of possible wrong answers only reduced the proportion of correct identifications by 5%. Corrections of a mass or abundance error in each of six reference spectra increase the database matching performance by as much as the addition of one spectrum of a new compound. A newly developed 'matching quality index' based statistically on these values indicates that the largest database is also by far the most effective for matching unknowns.

Despite recent advances in NMR and mass spectrometry, the structural identification of organic compounds in complex mixtures such as biofluids remains a significant analytical challenge. For mass spectroscopy applications, chemical identification is generally limited to determination of elemental formula. Hill et al. (see 'Further Reading' section) have tested the hypothesis that unknown chemical structures can be determined by matching their experimental collision-induced dissociation (CID) fragmentation spectra with computational fragmentation spectra of compounds retrieved from chemical databases. The monoisotopic molecular weights (MIMW ± 10 ppm) of 102 'test' compounds were used to download 102 'bins' from the PubChem database. Each bin contained the corresponding test compound and, on average, 272 other candidate compounds, including 158 compounds having the same elemental formula as the test compound. Commercially available software was used to generate fragmentation spectra for all compounds in each of the 102 bins. Experimental CID spectra for each of the 102 test compounds were then compared to the computational spectra in order to rank candidate compounds based on number of fragment MIMW matches. This method returned the test compound as the highest-ranking (or tied with the highest ranking) compound for 65 of the 102 bins. The test compound was ranked within the top 20 candidate compounds for 87 bins. In addition, the correct elemental formula was ranked first for 98 of 102 bins. Thus, matching experimental with computational fragmentation spectra is a valid method for rapidly discriminating among compounds having the same elemental formula and provides a novel approach for querying chemical databases for structural information.

Recently, three programs have been assessed by Schymanski et al. (see 'Further Reading' section) for their ability to predict mass spectral fragmentation patterns for all constitutional isomers of an experimental low-resolution EI-MSmass spectrum, given the molecular formula, and to use this information to identify the

Figure 9 Systematic structure elucidation using the molecular formula of the unknown, structural restrictions from automatic mass spectra classification and exhaustive isomer generation. Ethyl 2-(2-hydroxyphenyl)acetate is the 'unknown'.

'correct structure.' MOLGEN 3.5 was used to generate the structures, while whereas all spectra were extracted from the NIST database. The commercial programs Mass Frontier and ACD MS Manager, as well as MOLGEN-MSF (developed by the University of Bayreuth) were used to generate mass spectral fragments. MOLGEN-MSF was used to generate 'match values' to compare the different programs and their ability to identify the 'correct structure.' Although high match values could be achieved with certain settings, the ranking of the correct structure relative to other constitutional isomers was not significantly better than the results published previously and in some cases significantly worse. Furthermore, all programs showed bias toward specific structures, which changed significantly

with minor changes to the program settings. Thus, advances in mass spectral fragment prediction have not necessarily improved computer-aided structure elucidation (CASE) from EI-MS and indicate that caution must be used when confirming the identity of a compound only based on the match between its predicted fragments and the mass spectrum.

Conclusions

The best worldwide performance has been claimed for more than one commercial MS database system. However, more neutral observers state that automated spectra interpretation systems have a rather limited scope.

Spectra library search systems are now widely used in MS laboratories and do a good job with routine problems. They are not so useful with complex problems or if the unknown is not contained in the library; however, current research promises considerable improvements of these methods in the future. The routine application of library search methods and spectra classification liberate the human spectroscopist from time-consuming, simple work or at least provides valuable preliminary suggestions for the expert.

Symbols

A	amplitude of motion
B_o	main electromagnetic field
D	time diffusion coefficient
D^*	apparent diffusion coefficient
G_s	gradient in the slice selection direction
$G_{y\max}$	maximum gradient value
J_m	m th-order Bessel function of the first kind
S	observed signal
S_m	signal of the m th order artefact
S_o	signal after full relaxation
S_{0ASAT}	residual T_{1A} signal after prolonged irradiation
S_t	signal after irradiation period t
T_1	longitudinal relaxation time
T_{21}	spin–spin relaxation time
T_A	first inversion period in a double inversion recovery sequence
T_{1A}	time constant of free pool of spins
T_{1ASAT}	time constant that defines development of saturation
T_{1OBS}	T_1 in the absence of any RF irradiation
T_B	second inversion period in a double inversion recovery sequence
y_f	field-of-view size in f -direction
y_v	voxel length in y -direction
α	excitation pulse flip angle
β	refocussing pulse flip angle
γ	gyromagnetic ratio
δ	pulse duration
ΔG_y	gradient movement
Δy	spacing in y -direction
θ	spin phase angle
θ_o	value of θ at the voxel boundary
v	velocity of flow
φ	phase change

Introduction

The key factor which has led to the huge growth and clinical acceptance of magnetic resonance imaging (MRI) is really quite fortuitous. This is that tissues have quite different values of T_1 and T_2 , and that, more importantly, the relaxation time constants of a great many diseased

tissues are quite markedly different from those of the normal structures surrounding them. Clinical MRI seeks to highlight these differences at the expense of all other considerations. As a result, all the methods used in traditional NMR have been investigated to find out if they can deliver maximal differentiation between normal and abnormal tissue. The manipulations are performed through complex sets of instructions issued to the various components of a machine at the correct times which are known as ‘sequences’. In the following sections we discuss the most important of these, and their variants.

Thereafter a number of phenomena are described which are both artefacts of images if care is not taken, and sources of desirable contrast under other circumstances. Included among these are such things as the effect of flow, a matter of great concern in medical imaging where data about the cardiovascular system is of substantial importance in many clinical conditions. Some of the implications of apparently *recherché* observations such as that of diffusion are very significant in the diagnosis of unexpected disease situations.

An important, though unfortunately brief, note discusses the single most significant artefact in MRI, arising from the physiological measurements of the patient. The problem of controlling the effect of respiratory motion in particular has delayed the application of MRI to the imaging of much of the thorax and abdomen very substantially.

Standard Sequences

Most clinical MRI revolves around the contrast generated by three very standard sequences, partial saturation, spin echo and inversion recovery, which are familiar to those working on traditional high-resolution spectroscopy, but having a resonance and significance in clinical MRI not found elsewhere. The notation used in this article for times and other sequence features is that proposed by the American College of Radiology, and generally used in human MR studies.

(Partial) Saturation Recovery Sequence

This is the classic α –TR– α sequence of NMR in imaging form. The sequence form, showing how the various gradients and RF pulses are manipulated for a spin-warp

data acquisition, is sketched in **Figure 1a**. The dotted lines indicate that the phase encoding gradient is varied from one acquisition to the next. The theoretical relationship for the sequence is:

$$S = \frac{S_0[1 - \exp(-TR/T_1)]\exp(-TE/T_2^*)\sin \alpha}{1 - \exp(-TR/T_1)\cos \alpha} \quad [1]$$

where S is the observed signal, and S_0 is that which is available after full relaxation and immediately prior to excitation. In this sequence TR is the time between successive excitations, while TE is the time from the centre of the excitation to the centre of the echo formed by the refocusing effects of the gradients. α is the actual flip angle. Note that this relationship is much simplified from that derived by solution (see below) of the Bloch equations, by assuming $T_1 \gg T_2$ and that off-resonance effects and spatial selection effects are ignored.

What this means in practice in terms of signal differences and behaviour is shown in **Figure 1b**. This (and other similar figures to follow) uses the values in **Table 1** for typical normal and abnormal brain tissue. It is the

Table 1 Tissues, and their parameters, used in the description of the main sequences

Tissue	T_1 (ms)	T_2 (ms)	Relative available proton density
White matter	670	85	0.7
Grey matter	920	95	0.8
Oedema	1060	150	0.9
Tumour	1410	200	0.9
CSF	2500	500	1.00
Fat	265	50	0.6

The relative available proton density column indicates the relative peak signal observable from the tissue. Cerebrospinal fluid (CSF) which has a signal near to that of pure water in normal subjects is taken as unity.

Figure 1 (Partial) saturation recovery sequence. (a) Sequence configuration. A flip angle of α is assumed in this diagram. (b) Calculated signal characterization for the tissues, the parameters for which are given in **Table 1**. α in this case is 90° . ($TE = 20$ ms for the purposes of this plot.) (c) The same characteristics as in **Figure 1b**, but with $\alpha = 30^\circ$. ($TE = 20$ ms for the purposes of this plot.) (d) Blipped echo planar sequence. An echo is formed during each excursion of the readout gradient, with a line of k -space being acquired at the same time. The bias pulse in the phase encoded waveform is used to control the starting point in k -space of the image acquisition.

differences between these components that decide the efficacy of MRI. The values in **Table 1** are typical of

$$S = \frac{S \exp(-TE/T_2)[1 - \exp(-TR/T_1)]\{\sin \alpha \cos \beta \exp(-TE/2T_1) - \sin \beta [1 - \exp(-TE/2T_1)(1 - \delta \cos \alpha)]\}}{1 + \exp(-TR/T_1)(\cos \alpha \cos \beta + \sin \alpha \sin \beta)} \quad [2]$$

those at 1.0 T. The coefficient, v , relating field and relaxation time constant variation for grey matter and white matter can be taken to be ~ 0.3 , for blood and oedema as ~ 0.2 , for tumour as ~ 0.1 and for cerebrospinal fluid (CSF) as being ~ 0.0 . Note that this implies a tendency for relative contrast levels to fall as the main field (B_0) increases. (Note: v is the coefficient in the term $(T_1 \propto B_0^v)$.)

Figure 1c shows how the contrasts obtained are radically affected by reducing α from 90° (the value in **Figure 1b**).

Echo planar imaging is an extreme example of this sequence. In this procedure, after a single excitation, one of the gradients (the readout gradient) is switched to form a series of echoes during each of which one line of k -space is acquired, while the equivalent of the phase encoding gradient is incremental in some way. Though the original form of the sequence was rather different, the sequence form in current use ('blipped' echo planar) is shown in **Figure 1d**.

Spin-Echo Sequence

The partial-saturation sequence is typically used with short values of TE (except in special circumstances) and is thus primarily dependent for its contrast on differences in T_1 (i.e. it has ' T_1 -weighting'). The spin-echo sequence, though it is poor from the point of view of discriminating between normal anatomical structures, has proved to be extraordinarily effective in identifying a very wide range of pathological conditions, once it had been successfully implemented using relatively long TR and TE to give ' T_2 -weighting'. Initially applied to normal anatomy by the current author more than 2 years before its successful application clinically, it had seemed more or less completely uninteresting for MRI. Unlike inversion recovery,

Figure 2a shows a typical sequence structure for a spin-echo acquisition. The simplified relationship governing the sequence is:

and

$$\delta = \frac{1 - \exp(-TR/T_1)}{1 + \exp(-TR/T_1)(\cos \alpha \cos \beta + \sin \alpha \sin \beta)}$$

where α and β are respectively the excitation and refocusing pulse flip angles. When these angles are respectively 90° and 180° (and α in eqn [1] is 90°) the relationships for the partial saturation and spin-echo sequences look misleadingly similar, with the difference between T_2^* and T_2 being the only apparent change. Spin echo was very popular in the early days of clinical MRI because it was robust, and tolerant of many machine defects. In practice, while still regarded as an essential screening tool, it is now seen as being a relatively blunt instrument in terms of the subtlety of contrast that can be obtained with it.

Figures 2c and **2d** show contrast characteristics for a value of TR less than that of typical normal tissue, and a value of TR substantially longer, respectively. The characteristics suggest how choice of sequence parameters can emphasize, or eliminate, contrast between any two tissues.

The fast spin-echo (rapid acquisition relaxation enhanced (RARE)) sequence is the spin-echo equivalent of echo planar imaging, and its structure is shown in **Figure 2e**. Contrast is manipulated by choosing at which point in the echo train the central point of k -space is acquired.

Inversion Recovery Sequence

Although two of the very early developers of MRI placed substantial weight on it, the inversion recovery sequence was regarded through much of the development of MRI in the 1980s as being a difficult sequence to operate, and saddled with long acquisition times. The sequence is shown schematically in **Figure 3a**, and is governed by the relationship:

$$S = S_0 \frac{\{[1 - \exp(-(TR - TI)/T_1)]\exp(-TI/T_1)\cos \beta \sin \alpha - [-\exp(-TI/T_1)]\{\sin \alpha + \exp(-(TR - TI)/T_1)\}\exp(-TE/T_2)\}}{1 - \cos \beta \cos \alpha \exp(-TR/T_1) + \sin \alpha \sin \beta \exp(-(TR - TI)/T_1)\exp(-TI/T_2)} \quad [3]$$

which generated spectacular contrast between normal tissues such as grey and white matter (see below), an inappropriate choice of the echo time (TE) can result in very little contrast indeed in normal organs (as **Figure 2b** suggests).

(where TI is inversion time) which simplifies to the familiar form:

$$S = S_0 \left[1 - 2\exp\left(-\frac{TI}{T_1}\right) + \exp\left(-\frac{TR}{T_1}\right) \right] \exp\left(-\frac{TE}{T_2}\right) \quad [4]$$

Figure 2 Spin echo sequence. (a) Sequence configuration. Both 90 and 180° pulses are shown as being selective. The splitting of the phase encoding gradient (one half being in the opposite sense to the other) is quite normal, as is the placing of the warping gradient before the 180° pulse. These help a little with artefact generation. (b) Spin-echo image taken with TR 860 ms and TE 20 ms, showing how small the contrast between normal tissues can become if an inappropriate choice of parameters is made. (Slice 4 mm; matrix 256 × 192; field of view 22 cm.) (c) Signal characteristics for the spin-echo sequence, for the tissues given in Table 1. $\alpha = 90^\circ$ and $\beta = 180^\circ$; in this case TR (800 ms) was about half that of the mean of the T_1 values of white and grey matter. (d) Signal characteristics as in (c), but with TR being three times that of the mean of the T_1 values of grey and white matter at 2400 ms. (e) Schematic drawing of the RARE sequence (shown in this case for an echo train of 8: the letters 'ETL' in a sequence description refer to this value). Actual sequences are much more complex and subtle.

Figure 3 The inversion recovery sequence. (a) The form of the inversion recovery sequence. The initial inverting 180° pulse is normally selective (as shown) but in some situations this is omitted. The data acquisition shown is a gradient recalled echo, but, very frequently, a spin echo is used. (b) Characteristics of the inversion recovery for different values of TI at fixed, relatively long, TR (greater than twice the mean value of the T_1 values of grey and white matter). Because of its importance in some inversion recovery sequences the fat characteristic is also included. (c) Inversion recovery image using real reconstruction (TR 2720 ms, TI 600 ms, TE 30 ms) (128×256 matrix, 25 cm field of view; 2 acquisitions; 6 mm slice). (d) Magnitude reconstruction of the same inversion recovery image data as in (c). The sequence was designed so that grey and white matter and CSF have opposite signs. (e) Sequence for a double inversion recovery acquisition. The terms on the figure are those used in eqn [5]. A gradient-recalled echo data recovery is shown, though spin echoes are very frequently used. (f) Double inversion recovery image of the brain of a volunteer with long TE (80 ms), leaving the cortex of the brain as the sole remaining tissue with substantial signal. (TR 6000 ms; T_A 2300 ms; T_B 245 ms; 3 mm slice; 128×256 matrix.)

when $\alpha = 90^\circ$ and $\beta = 180^\circ$. A gradient-recalled echo data acquisition is assumed for simplicity (as the equation, in its spin-echo form, becomes very cumbersome).

Tissue characteristics for the sequence, with a TR assumed to be long compared with the T_1 of both grey and white matter, are shown in **Figure 3b** for the same tissues as before, but with the addition of fat.

This sequence is unique in having both positive and negative signals and exploitation of this leads to its versatility. **Figure 3c** shows an image acquired with a typical TI in the brain using real reconstruction (i.e. retaining the sense of the signal signs). **Figure 3d** shows the same data reconstructed as a magnitude map. The TI was such that grey and white matter on the one hand, and CSF on the other, have signals of alternate sign. Regions where two tissues with alternate magnetization overlap show reduced intensities as their signals oppose each other. The black rims round the ventricles are very obvious, but the unwary investigator can readily mistake more subtle differences, due to this effect, as having clinical significance.

The special property of inversion recovery, that a value of TI can be chosen which results in no signal from anything with the appropriate T_1 , has turned out to be a surprisingly powerful tool. From eqn [4], when $TR > 3T_1$ (or thereabouts), in effect the null point is obtained when $TI/T_1 \approx \ln 0.5$. The use of this form of cancellation was first applied to fat (in the short tau inversion recovery (STIR) sequence). Because, generally speaking, tissues with long T_1 times also have substantial T_2 times (practically all of which are longer than that of fat), in practice this means that tissue contrasts dependent on T_1 and T_2 are cumulative for practically all components, giving the approach additional diagnostic power. At the other extreme, cancellation of CSF might not seem to be as obviously beneficial. However, CSF behaves not unlike pure water, and its T_1 and T_2 are very long. Artefacts from its very large signals (due to tissue pulsatility, in the main) contaminate very many of the spin-echo acquisitions, particularly those with longer TEs, and elimination of the CSF signals has turned out to have substantial diagnostic benefits, particularly in the cervical spine.

For simplicity all flip angles are assumed to be either 90° or 180° as appropriate. The sequence has had limited clinical application. An example of its use, to cancel the signals for white matter and CSF while using a long TE data acquisition to attenuate the fat signal, is shown in **Figure 3f**. The residual tissue is predominantly grey matter. Attempts to extend the method to use more inversions still are unproductive as the signal-to-noise ratio of the images becomes unacceptable.

Artefacts

Radiologists are trained to be suspicious of even slightly unusual results, and to examine them very carefully for the possibility that they are artefacts. Spectroscopists (and other more traditional investigators using NMR) are less aware of the possibility, though more conscious that there may be problems in multidimensional Fourier transform NMR. Nevertheless, such terms as 'F1 noise' used to describe something which is actually artefact is indicative of users' perceptions.

The utility of the majority of clinical MRI scans is, however, not limited at all by signal-to-noise ratio concerns, even in quite low fields, but by artefact. Since this is a function of signal, arising, in most instances, from any instability at all in the data set, in effect the value of MRI images obtained from a study is quite substantially independent of field level, but dictated by the performance of the machine in use, and the skill of the operators in positioning the patient, choosing the sequences to use, and in persuading the patient to remain still.

Artefact analysis is a huge topic in its own right, and no more than a very cursory glance at it is possible here. Two different forms of artefact will be considered in very broad outline, to illustrate two quite different errors that can occur. These are those arising from slice selection problems, and those due to motion artefact (which, ranging from the gross to the microscopic, is the most pervasive of all).

To illustrate slice selection problems, it is useful to begin with the fuller expression for selective excitation [2] for a partial saturation sequence:

$$S = S_0 \frac{\exp(-TE/T_2)[1 - \exp(-TR/T_1)]\sin \alpha}{1 - \exp(-TR/T_1)\cos \alpha - [\exp(-TR/T_1) - \cos \alpha]\exp(-TR/T_2)} \quad [6]$$

Two inversions (with the cancellation of signals from two tissues) have also been studied using the sequence shown in **Figure 3e**, which results in the relationship:

$$S = S_0 \left[1 - 2 \exp\left(-\frac{T_B}{T_1}\right) + 2 \exp\left(-\frac{T_A + T_B}{T_1}\right) - \exp\left(-\frac{TR}{T_1}\right) \right] \times \exp(-TE_2) \quad [5]$$

Note that this ignores effects due to the spatial localization process. Assuming the rather benign shape for the RF spectrum shown in **Figure 4a** (which has relatively sharp edges and little overshoot), **Figures 4b** and **4c** show, respectively, the predicted slice shapes for two tissues, one with $TR = 2T_1$, the other with $TR = 0.2T_1$. In a typical head image in which the range of T_1 values is ~ 12 (from fat at 250 ms to CSF at 3000 ms), the slice shape changes quite markedly from place to place across the image.

Figure 4 Slice selection artefact. (a) Target slice shape in a partial saturation data recovery (equivalent to the spectral distribution of the RF pulse). This is rather more rounded than is achieved in the best formulations, but has less in the way of undershoot and oscillation at the edges, than is typically achieved. (b) Predicted slice shape for a tissue with $TR = 2T_1$. Note that T_2 effects are ignored. The pulses in (a) and (b) are scaled in the same way. (c) Predicted slice shape for a tissue with $TR = 0.2T_1$. This pulse is scaled at twice that of those above.

Regions in which partial volume effects mean that a single voxel can include two tissues with dramatically different T_1 values result in very different shapes at either side of a single slice. It should be borne in mind that in slice selective MRI, the slice thickness dimension is usually the largest one in a voxel by a substantial margin (at least a factor of 2, and more usually 5–10). Measurements of tissue parameters made from such data must be treated with great care, and the appreciation that the signals may well be badly contaminated by unwanted material.

Motion artefact has proved to be one of MRI's greatest challenges, and the most intractable of problems. It is generally associated with abdominal motion, but can occur anywhere due to either voluntary or involuntary motion of the patient, or regular physiological effects such as blood pulsatility. Motion can be very large, or very small.

The periodicity of the effects is given by (for motion in the phase encoding direction; other directions have similar forms of relationship):

$$\frac{\Delta y}{y_f} = FNTR \quad [7]$$

where Δy is the spacing in the y (phase encoding) direction, y_f is the size of the field of view in that direction, F is the frequency of the motion, N is the number of averages of each phase encoding step which is acquired and TR is the repetition time.

Their amplitude is given by:

$$S_m = \left| F \left[J_m \left(\frac{\pi A \Delta G_y}{y_v G_{y \max}} \right) \right] \right| \quad [8]$$

for the m th ghost. F is the Fourier transform function, J_m the m th-order Bessel function of the first kind, ΔG_y , the gradient movement, $G_{y \max}$ the maximum value of the gradient, A the amplitude of the motion and y_v the length of a voxel in the y -direction. This assumes regular motion, which holds only to a limited extent. Irregular behaviour is largely unmodellable and probably not productively so in general.

A variety of methods are used to attempt to control the effects, ranging from rapid imaging with breath-holding, to the relatively sophisticated probability assessments used in the respiratory ordered phase encoding method, or attempts to use internal markers to detect motion (as in the Navigator methods). These techniques are aimed primarily at controlling effects in the phase encoding direction(s). In the readout or slice selection directions, methods such as motion artefact suppression techniques, which rely on the use of multiple gradient pulses to refocus tissues moving with first, second, third and potentially more motion orders, are quite effective.

Susceptibility Effects

Susceptibility effects have a significance for MRI that goes far beyond the concerns high-resolution spectroscopists have about them as a potential source of line broadening and loss of resolution in their spectra. This is because, as with so many things in MRI, they are also a means of generating contrast, and of recognizing disease patterns. Apart from effects in tissue adjacent to air (as in the sinuses) and, to some extent, trabecular bone, both components having significantly different susceptibilities to that of tissue, the important applications of susceptibility relate to the presence of blood. While oxygenated blood is diamagnetic (possibly more so than normal tissue), deoxygenated blood is mildly paramagnetic, while the degradation products of blood (found in haemorrhagic deposits) become increasingly strongly paramagnetic as they change from methaemoglobin, through haemosiderin to ferritin.

Susceptibility effects cause changes to both expected signal intensities and their phases, both of which can be observed in clinical MRI. The phase changes given by the mean field deviations in voxels with sides x_m , y_m , z_m and field deviation ΔB_{0xyz} at a point x , y , z inside them are:

$$\varphi = \frac{\gamma TE \int_{x=0}^{x_m} \int_{y=0}^{y_m} \int_{z=0}^{z_m} \Delta B_{0xyz} dx dy dz}{x_m y_m z_m} \quad [9]$$

while the amplitude differences are:

$$S = \left[1 - \exp\left(-\frac{TR}{T_1}\right) \right] \exp\left(-\frac{TE}{T_2}\right) \times \int_{x=0}^{x_m} \int_{y=0}^{y_m} \int_{z=0}^{z_m} S_{xyz} \exp(\gamma \Delta B_{0,xyz} TE) dx dy dz \quad [10]$$

where S_{xyz} is the available signal from location dz, dy, dx and $\Delta B_{0,xyz}$ is the local field deviation. TE is the echo time as usual. Relaxation effects have been assumed to be constant over the whole voxel.

For a linear gradient in the slice selection direction, for example, which is, as noted before, the largest dimension of typical voxels, the result is:

$$S = [S_0 \text{sinc } \theta]_{-\theta_0}^{+\theta_0} \quad [11]$$

where $\theta = \gamma G_s TE$, with G_s being the erroneous gradient in the slice selection direction and θ_0 is the value of θ at the voxel boundary.

Susceptibility effects have taken on a great significance in MRI, in the form of the suggested basis of the blood oxygen level-dependent (BOLD) approach to the observation of brain function. The experiment is modelled as arising from the diffusion of water molecules in regions with changing concentrations of paramagnetic deoxyhaemoglobin.

Flow Effects

Apart from its tendency to generate artefacts, flow is very well visualized by MRI. The approaches used to measure flow are variants of the gradient method and have been developed as a quantitative method by Bryant et al. who used the flow sequence shown in **Figure 5**. Using the parameters shown in the figure the velocity of flow (v) is measured as a phase difference (φ) and given by

$$\varphi = \gamma G \delta \Delta v \quad [12]$$

Flow velocity is then linearly related to phase, though care has to be taken with the choice of sequence parameters to ensure that the velocities being measured do not exceed the available range (as the unrestrained signal pattern is a repetitive sawtooth, with consequent 'wrap round', and potential ambiguity).

Flow is used in a wide range of applications in MRI of which the most important is angiography. Basically there are two strategies used for this. One is 'phase contrast' based on a strategy derivative from eqn [12] but using very short echo partial saturation (or gradient recalled echo) sequences. The alternative method is the 'time of flight' approach, in which spins outside a region to be

Figure 5 Sequence for flow measurement. The parameters used in eqn [12] are marked on the figure. Note that the sensitizing pair of gradient pulses can be included in any of the gradients (or any combination of them).

studied are tagged in some way, and their future progress monitored.

Diffusion Effects

Diffusion effects have long been studied in NMR. The pulse sequence used is identical to that of **Figure 5**, though the gradient amplitudes are much larger. The relationship for the signal appropriate for an experiment involving tissue diffusion is:

$$S = S_0 \left[1 - \exp\left(-\frac{TR}{T_1}\right) \right] \exp\left[-\frac{TE}{T_2} - D\gamma^2 G^2 \delta^2 \left(\delta - \frac{\Delta}{3}\right)\right] \quad [13]$$

which can be reformulated as:

$$S = S' \exp\left(-\frac{TE}{T_2} - bD^*\right) \quad [14]$$

where

$$b = \gamma^2 G^2 \delta^2 \left(\delta - \frac{\Delta}{3}\right)$$

D^* (the apparent diffusion coefficient) can be calculated from the results of two experiments which are identical except for the values of b . (Note: the qualification by which this experiment is assumed to measure D^* and not D , the true diffusion coefficient, is a reflection of the uncertainty about the real diffusion process in tissue, as is further suggested in the next paragraph.)

However, the model for diffusion on which this theory is based assumes a uniform isotropic medium. In actuality, as evaluated in human subjects, diffusion in tissue is anything but isotropic. The coefficient can appear to be

quite different depending on the direction of sensitization. This topic is much too large to be covered adequately here, but the anisotropy is of surprising clinical importance, particularly in the study of stroke and the development of myelination in the infant brain.

Magnetization Transfer Contrast (MTC)

Another method which MRI has adopted from traditional NMR is MTC. This seeks to investigate chemical and magnetization exchange between what are typically NMR visible and invisible spin pools. Normally the system is modelled as having two pools (A, visible, and B, invisible in the experiment being performed), though three or more might be necessary to explain what really happens. This concept was applied to MRI, and it is possible to map the different behaviours of various tissues. The model is shown in **Figure 6a**, and the form of sequence used to implement the technique in **Figure 6b**. The prolonged irradiation that is used is applied off-resonance, and in the traditional experiment the amplitudes of the residual signal are plotted against the offset frequencies (at constant RF amplitude).

Figure 6 Magnetization transfer technique. (a) Two-pool model used for the evaluation. This is certainly a simplification of reality, although imaging data quality does not justify further elaboration. (b) MTC imaging sequence. A gradient-recalled echo data acquisition is used once more. The spoiler shown is used to dephase residual transverse magnetization after the end of the off-resonance irradiation period (of length t). Practical sequences of all types use pulses like this to eliminate the unwanted signals from spins pursuing complex patterns of excitation and recovery.

In MRI, useful contrast improvements are achieved by MTC in angiography and in haemorrhage studies. The time needed to achieve saturation of the pool with the broad-line has to be minimized in MRI (for thermal deposition reasons), and the effective time constant which applies is that appropriate to the signal relationship:

$$S_t = S_{0\text{ASAT}} + (S_0 - S_{0\text{ASAT}}) \times \exp\left(-\frac{t}{T_{1\text{ASAT}}}\right) \quad [15]$$

S_t is the signal after a period of irradiation t , $S_{0\text{ASAT}}$ is the residual signal after prolonged irradiation, and $T_{1\text{ASAT}}$ is the time constant which defines the development of saturation. T_{1A} is the time constant of the free pool of spins (in the absence of any exchange), is given by:

$$\frac{S_0}{S_{0\text{ASAT}}} = \frac{T_{1A}}{T_{1\text{OBS}}} \quad [16]$$

where $T_{1\text{OBS}}$ is the value of T_1 measured in the absence of any RF irradiation. The experiment needed to derive the data is one in which the signals are measured after various durations of irradiation and the effects in tissue can be substantial.

A common factor of both diffusion weighting and MTC can on the one hand be a highly desirable effect but can on the other hand be an artefact of other measurements, affecting, for example, the accuracy of measured time constants if not carefully monitored.

Conclusion

This has been a very brief review of a large, complex and still growing area. Contrast is a matter of obsessive importance to radiologists and as a result will continue to be investigated as long as new possibilities for its generation can be found. For anything outside the scope of this article, readers seeking more information are referred to the burgeoning literature. Useful major sources are given in the Further Reading section, and there are a great many more books discussing clinical contrast for particular tissue systems and structures.

Cosmochemistry is the field of science which investigates the composition and evolution of material in the universe and, in particular, in the Solar System. Cosmochemistry is intimately related to nuclear astrophysics, because almost all the chemical elements were synthesized by nuclear reactions in the interior of stars. The distribution of the abundances of the elements provides the basis for an understanding of the chemical and nuclear processes which determined their formation and evolution. The discipline of cosmochemistry therefore embraces the universe both in space and in time. Cosmochemistry requires a diverse range of observations and measurements of the elements, and in particular their isotopes, to understand the processes and events that shaped their past. Variations in isotope abundances are a vast information source, and their retrieval from mass spectra are of fundamental importance to cosmochemistry because of their unique isotopic signatures. Mass spectrometric isotopic abundance measurements are therefore crucial to unravelling our cosmochemical history. The role of mass spectrometry in providing isotopic information in areas such as 'cosmic' abundances, isotopic anomalies, cosmochemistry and planetary science, which are essential to our understanding of cosmochemistry, is the subject of this article.

Cosmic Abundances

Cosmic abundance tables of the chemical elements provide the basic data for theories of cosmochemistry and

nuclear astrophysics. The abundances are based on a variety of terrestrial, meteoritic, solar, stellar and cosmic ray data. **Figure 1** shows a schematic curve of the elemental abundances (normalized to Si equal to 10^6 atoms) as a function of mass number A . This curve is often referred to as the 'cosmic' abundance curve, but in reality the data is primarily of Solar System origin, and the curve is therefore representative of main sequence stars of similar age and mass as the Sun. However, since the overwhelming majority of stars have essentially solar compositions, the term 'cosmic' is of some relevance. Thus, first the distribution of the elements should be determined and then the processes should be understood which produced the relative abundances of these elements in the Solar System – and by inference in other parts of the universe. So the task of cosmochemistry, and its

Figure 1 A schematic curve of atomic abundance (relative to Si = 10^6) versus mass number A for the Sun and similar main sequence stars. The symbols s, r and p stand for the slow and rapid neutron capture processes and the proton capture process, respectively.

associated discipline nuclear astrophysics, is one of immense scope and importance.

Since the 1950s, when the elemental abundance distribution depicted in **Figure 1** became available, significant improvements have occurred in the accuracy with which the Solar System abundances are known. In part this is owing to the realization that Type I carbonaceous chondrites – made up of low-temperature condensates that escaped the many alteration processes which affected other classes of meteorites – closely approximate the condensable fraction of primordial Solar System material, and so represent our best opportunity of obtaining an abundance distribution which approximates reality. Isotope dilution mass spectrometry (IDMS) is an effective analytical method for determining trace element concentrations because of the excellent sensitivity, accuracy and precision of the technique, and because a quantitative recovery of the element concerned is not required. The abundance of the element is determined from the change produced in its isotopic composition by the addition of a known quantity of a tracer of that element whose isotopic composition is different from that of the naturally occurring element. IDMS has been used extensively in refining the Solar System abundance curve because it is ideally suited to analysing small samples – such as the Type C-I carbonaceous chondrites. Meteoritical elemental abundances can now be determined by IDMS at the 3% uncertainty level, although most of the Solar System abundances have an uncertainty of 10% or greater.

The canonical model of nucleosynthesis, which was developed to explain the elemental abundance distribution, is based on the assumption that presently constituted matter is derived from a mixture of numerous components synthesized by a number of processes with a variety of nuclear histories. The chemical elements are synthesized through a continuous process in which a fraction of the material is cycled through successive generations of stars. Apart from hydrogen, most of the helium and some lithium and boron, which were produced during the high temperature, high density stage of the universe, which is referred to as the ‘big bang’, the remaining elements were synthesized in the interior of stars by a combination of thermonuclear reactions (for the ‘light’ elements with $Z < 20$), nuclear statistical equilibrium processes (for the iron peak group of elements), and the slow (s) and rapid (r) neutron capture processes (for the ‘heavy’ elements with $Z > 31$).

The products of nucleosynthesis are returned to the interstellar medium by supernovae and by mass loss from red giants and novae. The processed and expelled material, isotopically enriched to varying degrees, is then incorporated in later generations of stars, where further nuclear processing takes place. Thus the Solar System was formed from material that has been processed by a

number of nuclear processes in a variety of stellar environments over the lifetime of the galaxy.

Isotopic Anomalies

The conventional wisdom of the late 1960s, based on the apparent isotopic homogeneity of Solar System materials, was that the memory of interstellar chemistry had been erased by a hot gaseous homogenization of pre-existing material from which the Solar System condensed. Technological advances in mass spectrometry, particularly in ion microprobe analysis, have enabled the isotopic composition of extremely small meteoritic samples to be measured with high precision in relation to ‘standard’ samples, and these analyses have revealed the presence of isotopic anomalies, some of which can be correlated with nucleosynthetic mechanisms occurring in stellar sites. Isotopically anomalous material provides compelling evidence that the Solar System is derived from compositionally different and imperfectly mixed nucleosynthetic reservoirs. Whilst considerable isotopic homogenization undoubtedly took place during the formation of the solar nebula and in planetary formation, some remnants of primordial material have been preserved in refractory inclusions and prestellar grains found in primitive meteorites.

Isotopic abundances are said to be anomalous if the measured isotopic ratios cannot be related to the terrestrial (and by inference solar) isotopic composition of elements through a mass fractionation relationship resulting from a natural physiochemical process, and the mass spectrometer measurement itself. The only variations in the isotope abundances in terrestrial materials occur by radioactive decay and by the physiochemical processes mentioned earlier. Thus, terrestrial samples serve as a good example of homogenized Solar System material against which anomalous isotopic material can be compared.

The first isotopic anomaly was discovered in 1960 in the noble gas Xe. The anomalies were of a dual nature – the so-called ‘special’ anomaly in ^{129}Xe which was shown to be caused by the presence of the extinct radionuclide ^{129}I , and the ‘general’ anomalies which occurred in most of the other isotopes (**Figure 2**). The pattern of enrichment in the heavy isotopes $^{136,134,132,131,130}\text{Xe}$, which is particularly pronounced in carbonaceous chondrites, became known as carbonaceous chondrite fission xenon, because it was hypothesized that these anomalies were produced by the spontaneous fission of a super-heavy element. Isotopic anomalies in Xe, and also Ne, made little impression on the cosmochemical community because the systematics of the noble gases were poorly understood and other explanations for the anomalies were forthcoming. It was not until isotopic variations

Figure 2 The mass spectrum of Xe extracted from the Richardton meteorite. The horizontal lines show the comparison spectrum of terrestrial Xe. The isotopes 124, 126 and 128 have been measured at 10 times the sensitivity of the remaining Xe isotopes.

were found in the abundant element oxygen in 1973 that the reality of isotopically anomalous material in meteorites was fully accepted.

Refractory inclusions

The fall of the carbonaceous meteorite Allende in 1969 was fortuitous in that it contained refractory inclusions – a logical location for the survival of presolar material – in sufficient quantity to enable extensive mass spectrometric investigations to be carried out on a wide range of elements. These inclusions, condensed from the cooling gas of solar composition, comprise refractory oxides such as spinel, perovskite, pyroxene and melilite and may contain isotopically anomalous material since they probably condensed before isotopic homogenization was complete. Oxygen consists of three isotopes, and thus in principle it is possible to distinguish between physiochemical and nuclear effects. The former produces fractionation that is linearly proportional to the relative mass difference $\Delta m/m$ and thus the measured $\delta^{17}\text{O}$ values would be approximately half the $\delta^{18}\text{O}$ values. Terrestrial samples fall on this fractionation line of slope 0.5 (Figure 3), whereas meteoritic materials yield values that

Figure 3 The isotopic composition of O in inclusions from carbonaceous chondrites which define a line of slope approximately unity in contrast to terrestrial samples which fall on a fractionation line of slope 0.5. SMOW is a terrestrial standard against which the per mil deviation δ of the oxygen isotopes is measured.

define a line of slope unity. This unexpected result was explained by arguing that a component of almost pure ^{16}O , produced by nucleosynthesis, was incorporated in meteorites. The δ notation is extensively used in mass spectrometric measurements to distinguish isotopic variations in a sample from a terrestrial standard. In the case of oxygen, the terrestrial standard is called ‘standard mean ocean water’ or SMOW. The δ values are customarily given as per mil deviations from the standard.

The elements of the iron peak group provide information on the late evolution of massive stars by nuclear statistical equilibrium processes. Any isotopic anomalies found in these elements would reflect variations in the quasi-equilibrium conditions of stellar interiors, provided that the isotopic abundances were not affected during their injection into the solar nebula. High-precision thermal ionization mass spectrometry (TIMS) has revealed correlated anomalies in the neutron-rich isotopes of Ca, Ti, Cr, Ni and Zn from refractory element-rich inclusions in carbonaceous chondrites. The magnitudes of these anomalies in Ca–Al-rich inclusions from the Allende meteorite are of the order of $\geq 1\%$. No single set of nuclear statistical equilibrium conditions can be found to explain the relative excesses in all the elements in these inclusions. However, a multi-zone mixing model has been proposed in which material from a number of stellar zones, with a variety of neutron enrichments, is mixed during the ejection of that material from a star. The magnitudes of the anomalies are affected by dilution with normal Solar System material, and by chemical fractionation processes that occur after nucleosynthesis has terminated.

Figure 4 shows the isotopic anomalies of the iron peak elements predicted by the multi-zone mixing model as compared with the average excesses as observed in

Figure 4 (a) Isotopic excesses of several iron peak elements as predicted by the multi-zone mixing model. They are given as ε units (parts in 10^4) relative to normal terrestrial isotopic composition. (b) Average excesses observed in normal Allende inclusions are displayed.

Ca–Al-rich inclusions. The match between the two data sets is impressive, except for Fe and Zn. In the case of Fe, no significant anomalies have been measured, but the multi-zone mixing model only predicts a ^{58}Fe excess of approximately 1 part in 10^4 , which is at the limit of present mass spectrometric capability. In the case of Zn, the excess in ^{66}Zn is approximately an order of magnitude less than that expected. This can be explained in terms of the volatility of Zn with respect to the other iron peak elements, as it would be the last of these elements to condense from the expelled stellar material. The correlation between anomalies in neutron-rich isotopes in the iron peak elements can therefore be explained in terms of the nuclear statistical equilibrium processes, which took place at a late stage in the evolution of massive stars.

The isotopic anomalies detected in the iron peak elements are extremely small (Figure 4), since the anomalous material is diluted with material with a terrestrial isotopic composition. This contamination results from the fact that the meteorite inclusion is taken into solution before chemically extracting the relevant element in a form suitable for conventional TIMS analysis. However, ion microprobe mass spectrometry can be used to analyse small meteoritic inclusions *in situ* without the need of chemical processing. This enables single inclusions to be analysed for a variety of elements, whilst

Figure 5 Ca and Ti isotopic compositions in hibonite ($\text{Ca}[\text{AlMgTi}]_{12}\text{O}_{19}$) inclusions displayed a large range from excesses in the most neutron-rich isotopes to deficits, while the other isotopes are close to solar proportions (defined as deviations, $\delta^{13}\text{Ca}$ or $\delta^{13}\text{Ti}$, in ‰). The most anomalous grains are both from the Murchison meteorite, 13-13 and BB-5 which have large excesses and large depletions respectively in ^{48}Ca and ^{50}Ti (insets). The ^{48}Ca and ^{50}Ti anomalies are clearly correlated and are inferred to come from neutron-rich supernova ejecta.

maintaining the petrographic context of the sample. The carbonaceous chondrites Murchison and Murray also contain refractory inclusions such as corundum and hibonite, but they are invariably small and difficult to analyse by TIMS. Ion microprobe mass spectrometry revealed that Ti anomalies in these hibonite inclusions were an order of magnitude greater than those found in Allende, presumably because hibonite has a higher condensation temperature than the assemblages of the Allende inclusions. Both excesses and deficits were measured in ^{50}Ti , and these anomalies were correlated with anomalies in ^{48}Ca (Figure 5). A number of morphological, chemical and isotopic features show marked correlations in Murchison refractory inclusions, which provides strong evidence that nucleosynthetic anomalies have survived through discrete inclusion-forming events in the early Solar System.

Presolar grains

The discovery of presolar grains was made possible by the development of chemical procedures in which carbonaceous meteorites were subjected to a stringent acid digestion regime. Carbon compounds such as diamonds, SiC and graphite were isolated in this manner and identified through their distinctive $\delta^{13}\text{C}$ pattern and anomalous noble gas component. These carbonaceous phases are samples of interstellar matter, which provide a window into the prehistory of the Solar System.

Although diamonds have the highest abundance of prestellar grains (400 ppm by weight of the bulk

meteorite), their average size is only 2 nm, which is currently too small for microanalysis. The diamonds exhibit a characteristic enrichment in the heavy and light isotopes of Xe (Xe-HL) as shown in **Figure 6**. The diamonds may have been produced by supernova shock waves passing through molecular clouds or from chemical vapour deposition. Individual grains of SiC may be up to 20 nm in size, which enables ion microprobe analysis of individual grains. These presolar grains contain measurable concentrations of a number of trace elements which has enabled isotopic anomalies in Si, C, N, Mg, Ti, Ba, Nd and Sm to be identified. Most of the heavy elements show evidence of s-process nucleosynthesis (**Figure 6**), whilst ^{12}C and ^{15}N enrichments show evidence of a mixture of CNO-cycle material with isotopically normal C and N. A minor fraction of the SiC grains have excesses in the decay products of short-lived

radionuclides, indicating that they may represent C-rich zone material from the outer layers of a supernova. The third carbonaceous presolar grain material, graphite, represents less than 2 ppm by weight of these primitive meteorites, and only a fraction is isotopically anomalous. Graphite spherules show a large range in anomalous C, and also contain small inclusions of refractory carbides of Si, Ti, Zr, Mo and W. Some s-process anomalies occur in Zr, suggesting that some of the graphite grains were produced in Asymptotic Giant Branch stars.

It was fortuitous that the resistance to acid digestion of presolar carbonaceous material led to their discovery. In the digestive procedures adopted, silicates and oxides are destroyed. It is hypothesized that most interstellar grains in the solar nebula are oxides, but apart from corundum (Al_2O_3) grains it has not been possible to isolate interstellar oxides. Furthermore the abundance of corundum grains is very small, although they do show isotopic anomalies in ^{26}Mg , ^{17}O and s-process Ti.

Figure 6 Progressive enrichment of isotopically exotic Xe components led to the discovery of interstellar diamond and SiC. The light and heavy components of Xe-HL cannot be produced in the same nucleosynthetic event and are probably the result of mixing. The Xe-S component from SiC reflects a mixture between the composition produced in s-process nucleosynthesis and a near-normal component of Xe.

Cosmochronology

One of the most challenging tasks in cosmochemistry is to place a time scale on the events that have occurred in the formation and evolution of the Solar System and for the nucleosynthesis of the chemical elements. **Figure 7** is a schematic diagram of the major epochs in the history of the cosmos, as described in the figure caption.

The dating of terrestrial materials (geochronology) does not provide any significant information on cosmochronology, but as early as 1953 an estimate for the age of formation of the Solar System was obtained from U–Pb isotopic analyses on meteoritic lead. Subsequently

Figure 7 Schematic diagram of the history of the universe. The first epoch T represents the time period from the 'big bang' to the isolation of the solar nebula from galactic nucleosynthesis and the solidification of Solar System bodies, while the third epoch T_{ss} represents the age of the Solar System. The shape of the production rate for nucleosynthesis is for illustrative purposes only.

meteorites were dated by the U–Pb technique to give an age of $4.551 \pm 0.004 \times 10^9$ years, and the fine-scale separation of events that took place during planetary formation can be resolved down to a few million years.

Numerous chronological investigations of lunar materials were carried out in the 1970s resulting in the chronology depicted in **Figure 8**. Crystallization ages of $\sim 4.6 \times 10^9$ years have been obtained from lunar rocks, so that there is a good correspondence between the meteoritic and lunar data for the time of planetary formation. The melt rocks derived from impact metamorphism gave ages of $3.85\text{--}4.05 \times 10^9$ years. This is interpreted as the result of a major bombardment of the Moon by small planetary bodies, which created the lunar basins and implies widespread bombardment of the Solar System during this time. After the termination of this bombardment phase, there was decreasing activity until approximately 3×10^9 years ago, after which the lunar surface appears quiescent.

To obtain accurate dating it is necessary to select a decay scheme whose half-life is of similar magnitude as the age of the event to be measured. Fortunately nature has provided a number of radionuclides with half-lives from 10^5 to 10^8 year which have given us the ability to place tight radiometric constraints on the chronology of nebular and planetary events in the early Solar System, and even on nucleosynthetic events that influenced the presolar molecular cloud before its collapse (**Table 1**). The radionuclides listed in **Table 1** are extinct in that they cannot be directly observed at the present time. Their prior presence must be inferred from an excess in their daughter product linked to the magnitude of the parent:daughter ratio.

The first mass spectrometric evidence of the presence of an extinct radionuclide in meteorites was ^{129}I , which, with a half-life of 16×10^6 years, produced an excess of ^{129}Xe (**Figure 2**). In the 1970s a study of refractory inclusions from Allende gave an excess in ^{26}Mg , the

magnitude of which was correlated with the abundance of Al in the samples (as shown in **Figure 9**). A plausible explanation is that ^{26}Al , with a half-life of 0.74×10^6 years, was present in these minerals and that the decay was in situ. **Figure 9** is a typical isochron diagram, so useful in geochronology, and the slope of the linear array enables a formation age Δ of $\sim 10^6$ years to be calculated. Another important discovery was that of excess ^{107}Pd in iron meteorites, resulting from the decay of ^{107}Pd (with a half-life of 6.5×10^6 years), which gave a value for Δ of $\sim 10^7$ year.

Table 1 lists the extensive isotopic evidence for these extinct radionuclides, which demonstrates that the time between the cessation of nucleosynthesis and the

Table 1 Short-lived radionuclides

Parent isotope	Daughter isotope	10^{-6} Half-life (y)	Early solar system abundance

Figure 8 Schematic diagram showing the chronology of major lunar events.

Figure 9 An 'isochron' diagram of $^{26}\text{Mg}:^{24}\text{Mg}$ versus $^{27}\text{Al}:^{24}\text{Mg}$ for minerals from an Allende inclusion. The linear dependence of the magnitude of the anomalous ^{26}Mg on the Al:Mg ratio can be interpreted as resulting from the decay of the radioactive nuclide ^{26}Al .

formation of meteorites was so short that it supports the hypothesis that a 'last minute' injection of nucleosynthetic products may have accompanied a supernova shock wave which triggered the collapse of the solar nebula. In this case, it is likely that some of the nucleosynthetic products may not have been well mixed in the molecular cloud from which the Solar System evolved.

Unlike the situation with extinct radionuclides, there are few long-lived radionuclides which are appropriate to measure the period of nucleosynthesis in that part of the interstellar medium from which our Solar System formed approximately 4.6×10^9 years ago. Various models have been developed to measure the mean age of nucleosynthesis T_i and ^{232}Th , ^{235}U , ^{238}U and ^{187}Re have been used to calculate T_i but the estimation of nuclear production rates is a difficult undertaking for each of these r-process nuclides. If one adds the age of the Solar System T_{ss} to estimates of the mean age of nucleosynthesis T_i taking into account big bang nucleosynthesis and stellar and galactic evolution, an age of the universe of $\sim 14 \pm 4 \times 10^9$ years can be obtained.

Planetary Science

Mass spectrometry is ideally suited to the investigation of planetary atmospheres and cometary material in terms of both elemental and isotopic abundances. Mass spectrometers have been an integral component of space probe instrumentation because they are mechanically robust, have a low power consumption, yet are sensitive and versatile.

Dust particle impact mass spectrometers were carried on space probes that approached close to Halley's comet in 1986. These are time-of-flight mass spectrometers of the design shown in **Figure 10**. The data confirm that the dust from the comet is essentially solar in both elemental and isotopic composition. A double focussing mass spectrometer was also used to determine the composition, density and velocity of the neutral gases and of low-energy cometary ions. This mass spectrometer showed that the neutral gas composition of the coma of Halley's comet was dominated by water vapour and other light element constituents. The third mass spectrometer carried on the Halley space probes was designed to determine the composition, density, energy and angular distribution of ions in the solar wind and cometary plasma. This ion mass spectrometer consists of two independent sensors – a high-energy range spectrometer and a high-intensity spectrometer. As the space probe Giotto approached comet Halley, H^+ , C^+ , H_2O^+ , CO^+ and S^+ were found in a diffuse shell-like distribution out to 3×10^5 km from the comet. As Giotto penetrated the atmosphere to within 1300 km to the nucleus of the comet, the main ion species were H^+ , H_2^+ , C^+ , OH^+ ,

Figure 10 Schematic diagram of the time-of-flight dust-particle impact mass spectrometer which was mounted in a space probe to examine the mass spectra of dust particles from Halley's comet.

H_2O^+ , H_3O^+ , CO^+ and S^+ . The gas and dust stream emitted from comet Halley contains a higher proportion of volatiles than is found in meteorites, which is consistent with the comet's original location in the cooler regions of the Solar System. Isotopic measurements show that O, S, C, Mg, Si and Fe in cometary and stratospheric dust particles are typical of those found in other Solar System material, implying that the dust has the same nucleosynthetic reservoir as the rest of the Solar System. However, isotopic anomalies in H and Mg confirm meteoritic evidence that some solid particles survived the homogenization processes that occurred in the early history of the Solar System.

The particle flux that is part of the expanding corona of the Sun is known as the solar wind. The elemental and isotopic composition of the solar wind was studied by various space craft in the period 1965–75, all of which carried electrostatic positive ion analysers. An ideal opportunity for further study was afforded by the Apollo mission to the Moon, in that aluminium foil collectors were exposed on the lunar surface in the Apollo 11–16 missions, which were then analysed for the noble gases by gas source mass spectrometry on the returned Al foil.

The lunar soil is an ideal repository for implanted solar wind elements, as are certain gas-rich meteorites. Deuterium is depleted relative to the terrestrial standard in these materials, the D:H ratio of $< 3 \times 10^{-6}$ being consistent with the hypothesis that D is converted into ^3He in the proto-Sun. Ion probe mass spectrometry has been used to study Mg, P, Ti, Cr and Fe which are present to enhanced levels in lunar minerals, indicating an exposure age of approximately 6×10^4 years. The isotopic data indicate that the light isotopes of a number of elements have been preferentially lost from lunar material because of volatilization by micrometeorites or solar wind bombardment. There is some indication, from a study of Ne in gas-rich meteorites, of a large solar flare

Figure 11 Schematic diagram of the high-performance, double focussing mass spectrometer used to measure the isotopic composition of the noble gases on IDPs.

irradiation during the early history of the Solar System, perhaps related to the T-Tauri phase of the Sun.

Isotopic studies of Gd, Sm and Cd from lunar samples show depletions in those isotopes which possess large thermal neutron capture cross sections. This has not only enabled the integrated neutron flux and neutron energy spectrum in the lunar samples to be determined, but has provided information on the stability of the lunar surface by analysing these elements and the noble gases in lunar core material.

Interplanetary dust particles (IDPs) can be collected on adhesive surfaces by U-2 aircraft at altitudes of 20 km, and a fraction of these have been identified as of non-terrestrial origin. Some of these IDPs have been analysed by gas source mass spectrometry using a double focussing instrument employing the Mattauch–Herzog geometry (Figure 11). The measured $^3\text{He}/^4\text{He}$ and $^{20}\text{Ne}/^{22}\text{Ne}$ ratios are lower than those observed in the solar wind. The sensitivity of static gas source mass spectrometry is such that stepwise heating of these IDPs has the potential to elucidate the thermal history of the stratospheric particles, which enables cometary and asteroidal origins to be differentiated.

Mass spectrometers were an integral component in the scientific payload of Viking Landers 1 and 2 and were designed to measure the composition and structure of Mars' upper atmosphere. Carbon dioxide is the major constituent of the atmosphere, whilst the isotopic composition of C and O in the Martian atmosphere is similar to that of the terrestrial atmosphere. However, ^{15}N is enriched in Mars' atmosphere by approximately a factor of 1.6. Certain meteorites have been identified as samples from the Martian crust. These SNC meteorites, including the orthopyroxenite ALH84001, on which claims for the evidence of life on Mars have been based, have

produced a large quantity of isotopic evidence which has been used in conjunction with the Viking Lander data. Since meteorites are delivered to our doorstep, free of charge as it were, it is important to acquire and classify new samples because of their potential value to planetary science.

Meteorites have provided the bulk of the data on which the 'cosmic' abundance distribution has been established, which led directly to the canonical theory of nucleosynthesis. A range of nucleosynthetic sites is now available for laboratory study, and nucleosynthetic models can be compared with measured isotopic compositions. Isotopic data on refractory inclusions and prestellar grains from primitive meteorites are a new source of astrophysical data, giving fresh insights into nuclear processes in stars. Isotope abundance measurements have also been invaluable in giving a cosmochronological time scale to the major events in the history of the universe. Mass spectrometers have been an essential component of the payload of space probes to the planets and Halley's comet, and technological advances have even enabled the noble gases in IDPs to be measured isotopically.

Symbols

D	self-diffusion coefficient
g	applied gradient strength, amplitude
J	magnitude of homonuclear spin coupling
T_1	longitudinal relaxation time
T_2	irreversible spin–spin relaxation time, transverse relaxation time
δ	duration of magnetic field gradient pulse
Δ	separation of magnetic field gradient pulses
γ	magnetogyric ratio
τ	time delay between RF pulses

The Magnetic Field Gradient Spin-Echo Method

Under the influence of a non-uniform magnetic field, otherwise equivalent nuclei at different locations give rise to different NMR frequencies. A linear magnetic field gradient along one sample axis will thus quantitatively map NMR frequency with a location along this axis. This is the basic tool used for NMR imaging and microscopy. However, it can also be used for the detection of transport phenomena such as diffusion and flow. The traditional and most widespread NMR method for measuring diffusion is based on the Hahn spin-echo experiment in such a field gradient. Under its influence a phase dispersion results in the rotating frame after application of the initial 90° RF pulse. However, if the NMR frequency remains the same during the whole experiment sequence a second RF pulse refocuses the spin dispersion and leads to the formation of a spin-echo. Normally a 180° pulse is used (applied at time t after the first RF pulse), and the spin-echo will thus appear at a time $2t$ (Figure 1). The effect of diffusion on this experiment is easy to work out – the random molecular movement from self-diffusion will partially change the location and NMR frequency of all nuclei in the sample in a

random fashion, leading to an incomplete refocusing of the echo. Originally these concepts and experiments were developed and performed in static magnetic field gradients (hence the notation SGSE – static gradient spin-echo). For SGSE experiments the echo attenuation is given by

$$A(2\tau) = A(0) \exp\left(\frac{-2\tau}{T_2}\right) \exp\left(\frac{-\gamma^2 g^2 \tau^3 D}{3}\right) \quad [1]$$

where T_2 represents the irreversible spin–spin relaxation time, g the strength of the applied gradient, D the self-diffusion coefficient of the molecule in question and γ the magnetogyric ratio of the monitored nucleus. It is evident that the echo attenuation effect is greatest for protons, but experiments on other nuclei are feasible.

Numerous developments of these procedures have been made since their initial discovery by Hahn in the

Excitation (90°_x -pulse) Dephasing Inversion (180°_x -pulse)

Figure 1 The basic 90°_x – 180°_x spin-echo experiment. (a) to (f) show the magnetization manipulation in sequence. In the case of diffusion measurements the cause of ‘fast’ and ‘slow’ spin vectors is that nuclei in different locations precess at different frequencies under the influence of the imposed magnetic field gradient. A useful supplementary picture of the phenomenon is to visualize a formation of a helical magnetization pattern in the sample along the gradient direction during the first gradient pulse, and the unwinding of this magnetization helix during the second gradient pulse. At the time of the echo peak, the net transverse magnetization is sampled and becomes the NMR signal.

early 1950s. Around 1965 the pulsed-gradient spin-echo (PGSE) experiment was suggested and tested. In its basic form it relies on the use of two linear magnetic field gradient pulses of amplitude ' g ', duration ' δ ' and separation ' Δ '; **Figure 2a**. Under these conditions the

Figure 2 The pulsed-gradient spin-echo (PGSE) experiment (a), and its stimulated echo analogue (b). Radiofrequency pulse phase cycling is required to isolate the stimulated echo from four other echo peaks that occur as a result of three RF pulses (at times $2\tau_1$, $2\tau_2 - 2\tau_1$, $2\tau_2 - 2\tau_1$ and $2\tau_2$).

amplitude of the spin-echo attenuates from its full value according to the so-called Stejskal–Tanner relation:

$$A(2\tau) = A(0) \exp\left(\frac{-2\tau}{T_2}\right) \times \exp[-D(\gamma g \delta)^2 (\Delta - \delta/3)] \quad [2]$$

The experiment is always made at a fixed value of τ , so as to keep the T_2 -attenuation effects constant. The main reasons for using pulsed gradients at the time were primarily to allow a variation of the observation timescale of the experiment [here equal to $(\Delta - \delta/3)$], to provide more experimental flexibility (in that Δ , δ and g can readily be varied over a large range of values), and to detect the echo in a relatively homogeneous magnetic field, thereby avoiding the necessity of using the (noisy) broadband spectrometer electronics needed for the detection of very sharp echoes. Fourier transform techniques in NMR that were developed some years later made it possible to make a frequency separation of the components of the echo (FT-PGSE), so as to provide a direct pathway to multicomponent self-diffusion measurements (**Figure 3a**). Of course, the homogeneous magnetic field

Figure 3 (a) A typical proton FT-PGSE data set from a complex solution sample (gelatin and two surfactants in D_2O , at 300 MHz). The experiment was based on a stimulated-echo PGSE sequence and made at fixed values of τ , Δ and δ , while varying the gradient current. The residual proton water peak is suppressed already at the lowest gradient setting. Figures (b)–(d) illustrate the application of a CORE analysis of this data set. CORE stands for COmponent RESolved spectroscopy. It is a computational approach that applies a global least-squares analysis to the whole data set, using the prior knowledge that component band shapes remain constant (see text). Band shape regions that are below 2% of the maximum intensity were omitted from the analysis. Two band shape components (gelatin and a common surfactant one) are found, which suggests that both surfactants diffuse at the same rate in this system and indicates the formation of a common aggregate.

during the PGSE detection period is an essential component in this context.

The T_2 relaxation is the main limiting factor of the magnetic field gradient experiment, especially when studying slow diffusion. Unfortunately there is an intrinsic correlation between short T_2 values and low D values in a given system. For this reason, the PGSE technique is not normally applicable to solids, and it is often also inapplicable to most heteronuclei. The overwhelming majority of studies are made on protons in solution.

In macromolecular systems in solution (where T_1 is often much longer than T_2) one can often lessen the effects of T_2 relaxation by instead applying the three RF-pulse stimulated echo (STE) experiment normally performed with three 90° pulses, at times 0, τ_1 and τ_2 – the stimulated echo appears at time $\tau_1 + \tau_2$; **Figure 2b**. Here the echo attenuation is given by

$$A(\tau_1 + \tau_2) = \frac{1}{2} A(0) \exp \left[-\frac{(\tau_2 - \tau_1)}{T_1} \right] \times \exp \left(\frac{-2\tau_1}{T_2} \right) \exp \left[-D(\gamma g \delta)^2 \left(\frac{\Delta - \delta}{3} \right) \right] \quad [3]$$

One should note that T_2 relaxation can be effectively suppressed, since it only occurs between the two first RF pulses (the spacing of which only needs to be slightly longer than the duration of the gradient pulse) and after the third. However, there are further advantages in using the STE experiment, especially in homonuclear coupled spin systems. By using a short first RF pulse interval one will also suppress effects of J -modulation. This is most often very signal enhancing since for complex spin systems J -modulation has effectively the same attenuation effect as very efficient T_2 relaxation. In addition, short- τ_1 FT-PGSTE spectra resemble normal absorption spectra, since the period during which J -modulation evolves is made small compared with $1/J$, where J represents the magnitude of the homonuclear spin coupling.

PGSE methods are the overwhelmingly dominant modes for measuring self-diffusion by NMR. It should be mentioned, however, that an RF field gradient analogue of the magnetic field gradient experiment has also been developed, but its use has not yet become widespread.

Other NMR techniques may be useful in certain situations, but are normally less powerful, or suffer from problems with regard to interpretation. Relaxation by paramagnetic species and intermolecular spin relaxation of protons, for example, are significantly dependent on translational diffusion rates. Separating these effects from other relaxation paths and translating them into self-diffusion data of the components is never straightforward.

Direct imaging of relaxation of the diffusional profile of a concentration gradient by NMR microscopy methods is sometimes a useful alternative approach to PGSE.

This is especially true in heterogeneous systems, where basic PGSE techniques may fail owing to rapid T_2 relaxation. One should note, however, that only one component can normally be imaged in a single experiment and that the quantity measured is mutual diffusion, rather than self-diffusion. The mutual diffusion coefficient is not directly translatable into a molecular displacement in space – rather it relates to the relative motions of the different components in the system.

Recent Methodological Developments

In the 1990s, the performance level of PGSE instrumentation increased by roughly two orders of magnitude with regard to most aspects, and the actual hardware became commercially available almost to the level of a standard spectrometer option. Consequently, PGSE methodological development and experimental application have greatly increased. To a large extent this is coupled to parallel developments with regard to field gradient equipment in NMR microscopy and imaging and to the development of pulsed field gradient methods for coherence selection and solvent suppression in high-resolution NMR.

Required equipment for high-performance PGSE on modern pulsed NMR spectrometers is a probe with self-shielded field gradient coils (i.e. having an auxiliary coil of opposite polarity – wound in such a way so as to cancel out the pulsed field gradients outside the actual sample volume) and a high-performance current-regulated gradient driver that can produce subsequent gradient pulses that match at the parts per million level with regard to area/shape. Present-day PGSE instrumentation is often capable of producing high-resolution FT-PGSE spectra at maximum gradient settings of 100–1000 Gauss cm^{-1} (1–10 T m^{-1}). This is typically made at maximum gradient current levels of 10–40 A, applied during 1–10 ms.

A general problem with PGSE measurements is that rapid switching of high gradient currents creates eddy currents in surrounding metal (probe housing, wires, supercon magnet bore) near the gradient coils. These effects, which last of the order of milliseconds, create disruptive time-dependent magnetic field gradients shortly after gradient switching. They can greatly disturb the experiment, but are dramatically suppressed by the above-mentioned use of self-shielded gradient coils. Further suppression can be achieved by selecting a larger-bore supercon magnet type, or probe housing metals other than aluminium (e.g. non-magnetic stainless steel). Notably, eddy current problems are almost completely absent in PGSE measurements made in resistive iron magnet geometries.

Eddy current suppression can also be achieved by using shaped (ramped) gradient pulse shapes (i.e. with much lower rise/fall times than for ‘rectangular’ pulses).

One should then note that the functional form of the eqns [2] and [3] assumes the use of rectangular gradient pulses and that the appropriate actual analytical expressions may be considerably more complicated if this is not the case. However, when the separation of the gradient pulses (Δ) is very large compared with their duration (δ) the expressions converge to a situation where only the pulse area matters. It can then merely be substituted as a 'corrected' quantity into, for example, eqns [2] and [3]. Two other remedies for the eddy current problem have also been suggested and used: (1) the so-called LED (longitudinal eddy delay) pulse sequence, where a further 90° pulse is appended to the experiment, so as to 'store away' the magnetization in the z direction (where it is unaffected by magnetic field gradients) until the magnetic field gradients from eddy currents have decayed. A further 90° pulse then reads back the longitudinal magnetization to create the echo in the transverse plane (2) the 'bipolar pulse pair', where two gradient pulses of equal strength, but of opposite polarity, are sandwiched closely around a 180° degree RF pulse. For large gradient

pulse separations this pair (for which eddy current effects cancel out to first approximation) effectively corresponds to a single (monopolar) gradient pulse of twice the length. Both approaches require appropriate RF phase cycling to work. For the LED pulse appendix to the stimulated echo sequence, no less than 32 cycling steps are needed. In the author's experience neither of these two latter methods are normally even needed nor recommendable if one uses a properly designed shielded gradient coil probe in a wide-bore magnet.

Considerable progress has also recently been made with regard to adequate data evaluation in the FT-PGSE experiment. The key point is that the entire band shape of a given component attenuates exactly the same amount with regard to the pertinent field gradient parameters in eqns [2] and [3], provided the experiment is made under conditions of a constant RF pulse interval setting. Consequently, a global minimization approach using this prior knowledge will result in direct extraction of the respective band shapes of components in the composite FT-PGSE data set (Figure 4a–4d). The main

Figure 4 (a) A synthetic FT-PGSE data set from a sample with two components that diffuse at rates of 2.0×10^{-10} and $2.0 \times 10^{-11} \text{m}^2 \text{s}^{-1}$ and (b,c) its CORE analysis. (d) The corresponding DOSY display, as based on the CORE analysis. In the diffusion direction, the width of the DOSY peak will reflect either or both of the error limits of the D value and the width of the D value distribution, as a result of, for example, the polydispersity of the component in question.

advantages of this approach is that all the information in the data set is accounted for. Therefore the effective signal-to-noise ratio of the experiment increases an order of magnitude as compared with an evaluation based on peak heights alone. It also allows confident application of the FT-PGSE method to multicomponent systems with extensive NMR signal overlap and closely similar component self-diffusion rates. Within the powerful computing environment of present-day NMR spectrometers this appears to be the natural way to proceed, even for routine work.

It has become popular to present results in a 2D manner, with spectral information on the x and z axes (frequency and intensity, respectively) and diffusion information on the y -axis. This display mode for FT-PGSE results has been named DOSY (diffusion-ordered spectroscopy). Its introduction did cause a little confusion in the literature with its unjustified implication of new types of experiments. One should note that a 'DOSY-display' is most often just based on interpolated individual single-frequency FT-PGSE data (or variants thereof) that are evaluated without taking account of prior knowledge about constant component band shapes with echo attenuation level. Nonetheless, although the DOSY display mode does not add any new information, it is appealing to the eye and has therefore undoubtedly stimulated the use and development of FT-PGSE-based techniques.

Finally one should note that two new variants of the original (static gradient) spin-echo experiment have been found to be quite useful, especially for systems where very slow diffusion and very short spin-spin relaxation rates prevail. One is based on the fact that commonly available superconducting magnets produce a dipolar-like stray field that has a very strong, stable and linear field gradient (at a lower than nominal, but still quite strong, magnetic field) a few 10 cm above or below the normal sample position. Thus, by pulling the probe out to the appropriate location one can monitor diffusion through the echo attenuation. In principle, this is possible on most modern supercon spectrometers. The notation STRAFI is often used for this type of stray field setup. The second variant is still quite unusual, and is based on sandwiching two supercon magnets in an 'anti-Helmholz' fashion. A preferred notation for both experimental setups is supercon-fringe field steady-gradient spin-echo (SFF-SGSE). One should note that this technique is not limited to protons – multinuclear measurements (e.g. protons and ^7Li) are straightforward in the same multinuclear probe. The intrinsic problems with SGSE experiments are (1) under the influence of a strong magnetic field gradient the RF pulses only excite a thin slice of the sample – the echo will therefore be quite weak and (2) actual echo detection is made in an inhomogeneous magnetic field, therefore the signal is very

sharp and Fourier transformation to separate its different components is not possible. In addition, the spectrometer must have broadband detection electronics, data acquisition filters disabled and a fast ADC to properly detect and sample the echo spike.

Applications of NMR Self-Diffusion Measurements

Self-diffusion data is intrinsically a very direct source of information. For unrestricted diffusion during a selected time span, the characteristic self-diffusion coefficient (D) simply translates into a mean square displacement in space ($\langle \Delta r^2 \rangle$) during the observation time (Δt) through the Einstein relation: $\langle \Delta r^2 \rangle = 6 D \Delta t$. One should note that under normal measurement conditions of PGSE techniques the mean square displacement of even large macromolecules during the characteristic time span of the experiment is generally very much larger than the average macromolecular diameter. Therefore the quantity ($\langle \Delta r^2 \rangle$) normally requires no further modelling and D values thus become very easy to interpret.

Diffusion in Simple Liquids

The NMR FT-PGSE approach is the only method that can provide quantitative information on multicomponent self-diffusion. Such data are central as a reference for, for example, theories of simple liquids.

Binding Studies

In binding studies the self-diffusion approach typically relies on a relative comparison of time-averaged self-diffusion rates between a 'bound' and 'free' state, meaning that in the simplest two-state situation the effective self-diffusion coefficient $D(\text{obs})$ will be given by $D(\text{obs}) = pD(\text{bound}) + (1-p) D(\text{free})$ where the degree of binding (p) may assume values in the range $0 < p < 1$. This equation can be rewritten into the form $p = [D(\text{free}) - D(\text{obs})] / [D(\text{free}) - D(\text{bound})]$. Hence, such experiments do provide the information needed to obtain binding isotherm information, for example, by a simple comparison of experimentally available self-diffusion coefficients. It is evident that the method is most suited for binding/aggregation of small molecules to larger entities and is most accurate at intermediate p values. Numerous such studies have been presented.

Non-Gaussian Diffusion in Macromolecular Systems

One should note that the Einstein relation $\langle \Delta r^2 \rangle = 6D\Delta t$ only holds in the limit of large Δt . 'Large', in this context, has a different meaning for small molecules and macromolecules. Uhlenbeck and Ornstein derived a generalized

relation, in their classical treatment of the subject back in the 1930s:

$$\langle \Delta r^2 \rangle = 6D \left\{ \Delta t - \tau_c \left(1 - \exp \left[\frac{1 - \Delta t}{\tau_c} \right] \right) \right\}$$

where the correlation time $\tau_c = m/f$, f being the coefficient of friction and m the mass of the Brownian particle. For small molecules in liquids the correlation time is of the order of a nanosecond, while the shortest imaginable NMR spin-echo experiments will exceed a fraction of a millisecond, but are more typically tens or hundreds of milliseconds. For macromolecules, however, this correlation time may be such that it affects (and thus becomes measurable by) the typical NMR PGSE experiment, when using appropriately selected measurement parameters (strength, duration and separation of gradient pulses). Only a few studies along these lines have appeared to date.

Non-Gaussian Diffusion in Heterogeneous Systems

In porous and heterogeneous systems, penetrant diffusion is not necessarily isotropic or Gaussian on a given timescale. PGSE techniques have been used since the early 1960s for characterizing such aspects of system morphology through the effects of non-Gaussian diffusion on the echo attenuation in the PGSE experiment. Restricted diffusion manifests itself in a variation of the apparent diffusion coefficient with the observation time (i.e. $\Delta - \delta/3$ in the PGSE experiment). A large number of system geometries and experimental conditions have been considered and analysed. Several complex pulse sequences have also been suggested for eliminating the effect of local magnetic field gradients that arise from susceptibility variations in the sample.

Another important development of experimental PGSE techniques applied to heterogeneous systems has been the discovery and utilization of so-called diffraction effects with regard to the attenuation of the echo, that is weak echo level maxima and minima that occur at high attenuation levels. In a system of spherical pores, for example, the system geometry manifests itself in a first echo maximum when the inverse of the pore diameter matches

the gradient setting $\gamma g \delta / 2\pi$. Mainly methodological work has been presented so far. Notably, the technique has also found use for the investigation of cell suspensions such as, for example, erythrocytes.

This article is reproduced from the previous edition, volume 1, pp 375–388, © 1999, Elsevier Ltd.

The purpose of this article is to briefly review the scope and potential of NMR as a non-invasive technique for studying drug metabolism. NMR has been used for the study of drug metabolism *in vitro* (biofluids, tissue extracts, biopsies, intact cells, perfused organs) and *in vivo* (animal models and human subjects). NMR spectroscopy is unique in its ability to permit both these kinds of studies. We shall see that the advantages and limitations of NMR as a tool for drug metabolism and disposition studies are different depending on the approach chosen (*in vitro* or *in vivo* studies). The first part of this article deals with the various isotopes used in such studies. The second part is a general discussion of the value and difficulties encountered with NMR in investigations on drug metabolism. In the third part, we have chosen some specific examples to emphasize the importance of NMR.

Isotopes Used in the Study of the Metabolism of Drugs by NMR

There are several NMR active nuclei (Table 1) that can be routinely used in drug metabolism and disposition.

The merits and disadvantages of some of these nuclei are discussed in the rest of this section.

Fluorine-19 (^{19}F)

The majority of studies in the literature concerns ^{19}F NMR mainly because of the favourable NMR characteristics of this nucleus, including a nuclear spin of $\frac{1}{2}$, relatively narrow lines, 100% natural abundance, high sensitivity (83% that of proton), large chemical shift range and short longitudinal relaxation times (T_1) which permit rapid pulsing with a corresponding improvement in the signal-to-noise ratio per unit time. Moreover, the negligible level of endogenous fluorine eliminates interfering background signals and dynamic range problems. As a number of fluorinated drugs are currently in clinical use, ^{19}F NMR offers a powerful method of monitoring their pharmacokinetics and metabolism either *in vitro* or *in vivo*. The main requirement is that drugs and metabolites should be present in minimal concentrations, near 10^{-3} mM, for studies in biofluids or 5×10^{-2} mM for *in vivo* studies.

Table 1 NMR isotopes for drug metabolism studies

Isotope	Spin	Natural abundance (%)	NMR receptivity ^a	Chemical shift range (ppm)	Minimum concentration (mM) for <i>in vitro</i> studies ^b	Minimum concentration ($\mu\text{mol g}^{-1}$) for <i>in vivo</i> studies
^1H	1/2	99.98	100	15	0.01	0.1
^2H	1	0.016	0.000 15	15	1.2	1.5

^aReceptivity (D) relative to proton (H) is a relative sensitivity figure used to compare signal areas theoretically obtainable at a given magnetic field strength: $D_X = [\gamma_X^3 N_X I_X(I_X + 1)] / [\gamma_{\text{H}}^3 N_{\text{H}} I_{\text{H}}(I_{\text{H}} + 1)] \times 100$ where γ is the magnetogyric ratio, N the natural abundance and I the spin quantum number.

^bIn biofluids.

^cWith an enriched drug and if an indirect method of observing protons coupled to the ^{10}B nuclei is employed.

^dWith an enriched drug.

^eOnly nitrogen centres with relatively symmetrical electron distributions can be studied.

^fFor organofluorine compounds.

^gChemical shift range of endogenous phosphorus compounds.

Proton (^1H)

The ^1H nucleus is present in all drugs, and has the highest NMR sensitivity of any stable nucleus. Moreover, it is the most abundant (99.98% natural abundance) of the two natural isotopes (^1H and ^2H or deuterium) of the hydrogen atom. However, the small chemical shift range and the extensive multiplicity due to homonuclear J -coupling sometimes make the observation and quantification of drug metabolites difficult. Moreover, ^1H NMR spectra of biofluids or tissues contain many intense resonances from water, proteins and lipids that must be reduced or eliminated. A simple method for water suppression (which nevertheless implies a treatment of the biological sample) consists in freeze-drying the sample and redissolving it in D_2O . Several NMR techniques are used to achieve the suppression of water and macromolecule resonances. The form of water suppression most commonly used is presaturation of the H_2O resonance using a secondary irradiation field at the solvent resonance frequency. A second approach takes advantage of the short T_2 (transverse relaxation time) of tissue water, proteins and some fats and consists in applying a spin-echo sequence that will suppress the broad resonances of water and macromolecules. Presaturation and spin-echo sequences can also be combined. Despite these drawbacks, several studies have shown that this nucleus can be exploited for the detection and measurement of drugs and metabolites in biofluids, i.e. for *in vitro* studies. The main requirements are that metabolites should have suitable protons and be present at concentrations 0.01–0.1 mM. As ^1H is a poor nucleus for the *in vivo* monitoring of drugs and metabolites, *in vivo* ^1H NMR spectroscopy has so far had little application. The reasons for this are manifold. Because of factors such as tissue heterogeneity, restricted molecular mobility, magnetic field inhomogeneity over the relatively large sample volume and the use of lower magnetic field strength spectrometers, *in vivo* signals linewidths are substantially broader than those obtained *in vitro*, in biofluids, for example. There is thus excessive signal overlap due to the very large number of signals that occupy a small chemical shift range and the signals from endogenous metabolites may obscure the detection and quantification of the drug and its metabolites. Moreover, the replacement of H_2O by D_2O becomes impractical for studies carried out on whole animals or humans since high concentrations of D_2O are toxic and D_2O is very expensive. More elaborate NMR techniques than those reported earlier are thus required for solvent suppression and spectral editing.

Carbon-13 (^{13}C)

One advantage of ^{13}C NMR is that its large chemical shift range enables reliable structural identification. However, although the carbon nucleus is found in all

drugs, the magnetically active isotope (^{13}C) is neither abundant nor particularly sensitive. These drawbacks combined with the low concentrations of drugs and their metabolites in biological systems make this nucleus in its natural abundance rather hard to detect. Improved sensitivity can be attained with polarization transfer experiments which partly transfer the favourable properties of the proton to ^{13}C . Furthermore, ^{13}C -enriched drugs can be synthesized to increase the NMR sensitivity. However, to obtain a full picture of the chemical changes taking place, several key positions usually need to be labelled. This may be chemically difficult, presupposes an *a priori* knowledge of the metabolism of the particular drug and is rather expensive in practice. It should be stressed that the label still needs to be present at millimolar concentrations, rather than the trace quantities that are typically required for radiolabelling studies. Because of these difficulties, the use of ^{13}C for *in vitro* or *in vivo* NMR studies of drug metabolism and disposition has been very limited.

Phosphorous-31 (^{31}P)

The ^{31}P nucleus is readily detected as it has a 100% natural abundance and is relatively sensitive. The presence of endogenous phosphates and derivatives (phosphomonoesters, phosphodiester, etc.) may interfere with signals from phosphorylated drugs and their metabolites. In practice, this is not a large obstacle as there are relatively few endogenous compounds that produce detectable signals. In the studies carried out to date, no interference in NMR signals between phosphorus-containing drugs or metabolites with endogenous compounds, apart from inorganic phosphate, have been described. As phosphorus-containing drugs are fairly rare, only a few ^{31}P NMR drug studies have so far been carried out.

Lithium-7 (^7Li)

The major lithium isotope, ^7Li , has a high NMR sensitivity. Since ^7Li is not a spin $I = \frac{1}{2}$ but a spin $I = \frac{3}{2}$ nucleus, it possesses a quadrupole moment, which gives rise to broad spectral lines. ^7Li NMR is not hampered by interference with endogenous signals. The only studies to date involve the *in vivo* determination of the pharmacokinetic profile of lithium salts.

Boron-10 and Boron-11 (^{10}B , ^{11}B)

NMR is a potentially valuable technique for evaluation of boron neutron capture therapy (BNCT) agents since both boron isotopes are magnetically active. The ^{11}B isotope has better sensitivity (16.5 versus 2% relative to ^1H) and higher natural abundance (80.4 versus 19.6%) than ^{10}B . Even though ^{10}B is the active nucleus for

neutron capture in BCNT, ^{11}B is more appropriate for NMR studies except if an indirect method of observing protons coupled to the ^{10}B nuclei is employed.

Other Nuclei

Deuterium (^2H), tritium (^3H), ^{17}O , ^{15}N , ^{14}N and ^{195}Pt suffer from several problems which cannot be overcome easily, including low sensitivity (^{17}O , ^{15}N , ^{14}N , ^2H , ^{195}Pt), poor resolution and broad signals (^{17}O , ^{14}N , ^2H), and the radioactivity (^3H) associated with the relatively high concentrations required for NMR studies. The sensitivity of detection can be improved by isotopic enrichment combined with enhancement by polarization transfer from proton. Nevertheless, all these problems are reflected in the limited use of these nuclei in NMR studies both *in vitro* or *in vivo*.

Advantages and Limitations of NMR for Drug Metabolism Studies

In Vitro Studies

Many analytical techniques, especially chromatographic methods, are in routine use for the analysis of biofluids. The reasons for the additional use of NMR spectroscopy are manifold and lie in the unique properties of NMR spectroscopy (Table 2).

Table 2 Advantages and drawbacks of *in vitro* NMR for drug metabolism studies

Advantages	Drawbacks
No destruction of the sample	NMR spectrometers are expensive instruments
No sample pretreatment necessary	Critical problem of peak overlap in ^1H NMR.
No degradation of unstable metabolites due to sample treatment	Resonances of the drug and metabolites must occur in spectral regions which are free of signals from endogenous metabolites
All metabolites are detected simultaneously in a single analysis	The volume of biofluid needed for NMR analysis might be large
Does not require preselection of conditions based on a knowledge of the compound to be analysed	NMR is relatively insensitive; this limits its use to the observation of drugs that are present at relatively high concentrations
An analytical technique does not have to be designed for each new application	
NMR gives both structural and quantitative information	
Little or no spectral interference from endogenous molecules in ^{19}F , ^{31}P , ^7Li and ^{13}C NMR	

NMR is non-destructive and enables the direct study of any intact biofluid without resort to treatment. Problems of extraction recovery and chemical derivatization, and those that may be encountered with pH-sensitive metabolites, are consequently avoided. NMR spectroscopy is thus particularly suited to the study of delicate samples.

The method is non-specific and unexpected substances are not overlooked during the investigation, since all metabolites (provided they bear the nucleus under observation and they are present at sufficient concentrations) are detected simultaneously in a single analysis. This contrasts with chromatography which usually requires some prior knowledge of the structures of metabolites to optimize sample preparation and detection. Novel metabolites may therefore be missed. NMR also avoids the use of a number of different chromatographic techniques, which is sometimes necessary when metabolites have different chemical structures. This is an important attribute of NMR in the search for novel metabolites when, often, the analyst will have no idea of the type of molecule to look for.

The NMR spectrum contains much structural information, and the observed chemical shifts and spin-spin coupling patterns can provide valuable clues about the structure of novel metabolites. Even though metabolites must still be extracted and purified for unequivocal elucidation of the structure, the NMR 'behaviour' nevertheless can give a good estimate of the structures of unknown compounds.

Although optimization of the quantification of drugs and metabolites in biofluids by NMR is somewhat tedious (choice of a suitable standard, determination of the T_1 , checking that excitation is uniform over the whole frequency range when a large spectral width is observed (often the case in ^{19}F and ^{13}C NMR), taking into account the heteronuclear nuclear Overhauser effect when proton decoupling is applied, validation of the assay, etc.) it is nevertheless fairly easy to obtain quantitative data, and NMR can be used routinely in the same way as HPLC. More-over, given a good signal-to-noise ratio, NMR can quantify substances accurately and reproducibly. Quantification in plasma and bile may nevertheless be affected by the binding of drugs or metabolites to macromolecules. This results in substantial signal broadening and gives a reduced signal-to-noise ratio or even leads to NMR-invisibility. Some sample pretreatment may be required in such cases.

Set against these advantages, however, are a number of disadvantages which need to be taken into account.

NMR spectrometers are expensive instruments, with the cost rising steeply with the field strength of the magnet used; higher field strengths provide greater spectral dispersion and yield better sensitivity. However, the magnets have long useful lifetimes (~15 years) and

the electronic components may be upgraded continuously at reasonable cost.

Although there is little or no spectral interference from endogenous molecules using ^{19}F , ^{31}P , ^7Li and ^{13}C (since ^{13}C -enriched drugs are required NMR), the problem of peak overlap is critical in ^1H NMR since the signals of a large number of endogenous compounds are present in a relatively narrow chemical shift range. Moreover, suppression of the intense signal from water is a prerequisite for ^1H NMR spectroscopy of biofluids. Resonances of the drug and metabolites must occur in spectral regions which are free of signals from endogenous metabolites. With a spectrometer operating at a field $\geq 9.4\text{ T}$, and taking the necessary precautions, drug metabolite resonances may be measured on the entire spectrum, except between 3.5 and 4.1 ppm as this range contains many overlapped resonances from endogenous molecules. In most biofluids, the region of the spectrum deshielded from the water signal is relatively low in interfering resonances, so that aromatic or heterocyclic drugs can often be studied with relative ease. The positive aspect of this limitation is that information can be obtained on alterations in composition of the biofluid after drug administration since the ^1H NMR spectrum of a biofluid gives a characteristic pattern of resonances for a range of important endogenous metabolites.

The volume of biofluid needed for NMR analysis ranges between 0.3 and 0.4 or 1.5 and 2.5 ml with 5 or 10 mm tubes, respectively. This can be a hindrance for pharmacokinetic studies which require numerous plasma samples or for difficult-to-obtain biofluids such as bile, cerebrospinal fluid (CSF) or those from neonates. The increased use of flow-injection NMR probes is alleviating this disadvantage.

Compared with most chromatographic and other spectroscopic techniques, NMR is relatively insensitive, which represents the principal drawback of the technique and limits its use to the observation of those drugs that are present at relatively high concentrations. It is difficult to give a precise figure for the minimum concentration requirement because there are many factors that influence the signal-to-noise ratio. The theoretical detection limit for ^1H NMR is around 10^{-3} mM for 600 MHz spectrometers using a 5 mm probe, but in practice it is often difficult to accurately quantify substances found at concentrations below 0.1 mM. With one currently available spectrometer (7 T, corresponding to a proton resonance frequency of 300 MHz) the detection threshold in a 10 mm diameter tube is $5 \times 10^{-3}\text{ mM}$ and 10^{-2} mM for 10 to 15 h of ^{19}F NMR or ^{31}P NMR recording. With a 11.7 T spectrometer (corresponding to a proton resonance frequency of 500 MHz) a detection threshold of 1 to $2 \times 10^{-3}\text{ mM}$ has been achieved in 12 h of ^{19}F NMR data acquisition in 10 mm tubes. However, the accuracy and reproducibility of the NMR concentration determinations

are generally $\leq 10\%$ for concentrations $\geq 5 \times 10^{-2}\text{ mM}$ for ^{19}F and ^{31}P NMR. For lower concentrations, the accuracy and reproducibility decrease and depend on the measurement time and the resulting signal-to-noise ratio in the spectra.

However, in spite of these difficulties, NMR spectroscopy has now become a technique of demonstrated utility and of unique ability in the analysis of biofluids. Moreover, the development of using separation methods in conjunction with NMR spectroscopy has given rise to a radical new approach in biofluid metabolite analysis. The coupling of HPLC to NMR in 1992 in the form of a commercially available instrument has been shown to be of great use in separating and determining the structure of drug metabolites in biofluids. The sensitivity of conventional HPLC-NMR provides a detection limit of approximately 150 ng of analyte for an overnight data accumulation. This technique has been extended to other chromatographic techniques such as supercritical fluid chromatography and to the use of nuclei other than ^1H or ^{19}F which form the basis of most studies so far because of their high NMR sensitivity. Another major development has been the combination of both NMR and mass spectrometry to an HPLC system, which will be of great help to elucidate the structures of drug metabolites in biofluids. The implementation of cryogenically cooled probes has also improved detection limits considerably.

The advantages and limitations of NMR for biofluids also apply to the analysis of excised tissue samples or intact cells packed in NMR tubes. For quantitative studies, the metabolites of interest should not be degraded by enzymes even at 4°C . For the analysis of cells, one must make sure that the density of the cellular suspension does not change with time, so that there should be no sedimentation in the NMR tube. This can be checked by acquisition of successive data blocks. The spectra are then examined individually, and if there is little or no change in metabolite levels, spectra can be added together to improve the signal-to-noise ratio. In such samples, there is often considerable signal broadening owing to inhomogeneities in the medium analysed and signals from compounds with similar chemical shifts may merge into a single peak. The ^{19}F NMR detection threshold at 470 MHz was found to be approximately 5 nmol g^{-1} of tissue or cellular suspension for 1–2 h measurement on 0.5–1 g samples. It has been shown that it is possible to obtain high-resolution ^1H NMR spectra of biopsy tissues simply by spinning at the magic angle ($\theta = 54.7^\circ$) at modest speeds (around 3 kHz). This could open up new routes of monitoring drug metabolism.

In Vivo Studies

The main interest of *in vivo* NMR is obvious. Measuring drug levels in plasma does not always reflect the drug

concentration at the receptor sites, which are generally located in the tissue cells of the target organ. Consequently, a method that allows one to measure the concentration of drugs and their metabolites *in situ* may be extremely useful. The principal advantages and disadvantages of carrying out drug metabolism studies using *in vivo* NMR are summarised in Table 3.

In vivo NMR spectroscopy can be used repetitively on the same patient since it is non-invasive. The ability to monitor the pharmacokinetics of a drug and to evaluate the potential modifications in drug metabolism could prove extremely valuable in patient management.

However, there are three main obstacles to the use of NMR *in vivo*. The first and major limitation is the lack of sensitivity. The minimum detectable concentration (Table 1) depends on many factors, including magnetic field strength, intrinsic sensitivity, presence of background signal, data collection time and sample size. The tissue concentration necessary for *in vivo* detection of a drug is typically 1–10 times that necessary *in vitro*. Order-of-magnitude detection limits for endogeneous metabolites are $0.2 \mu\text{mol g}^{-1}$ for ^{31}P and $0.1 \mu\text{mol g}^{-1}$ for ^1H . The *in vivo* ^{19}F NMR detection limit of 5-fluorouracil (FU) and its metabolites has been estimated at around $0.05 \mu\text{mol g}^{-1}$ with a 7 T vertical bore magnet for a 1 h measurement and $0.1 \mu\text{mol g}^{-1}$ with a 1.5 T whole-body spectrometer for total measurement time that is tolerable (30 min) for patients. It should not be forgotten that these detection limits are for molecules with unrestricted mobility, which is not always the case since drug and metabolites are often strongly bound to macromolecules or cell membranes.

The insensitivity of NMR has two consequences. First, prolonged data acquisition may be required to obtain satisfactory spectra. This is because the confident detection of resonances requires a good signal-to-noise

ratio, which is proportional to the square root of the number of scans performed. The kinetics of drug metabolism or elimination must therefore not be too rapid. Second, the surface coils used for the detection of drugs and metabolites *in situ* are relatively large, particularly in humans. The observed signals may thus have various anatomical origins (e.g. tumour tissue and normal tissue). To get a specific pharmacokinetic profile from one tissue, spatially localized spectroscopy using field gradients to define the volume of interest is useful. However, the relatively low concentrations of metabolites encountered have so far limited the use of this method for drug metabolism studies.

The second limitation is the lack of resolution. NMR signals observed *in vivo* are broad, and chemically similar compounds may not be readily distinguished.

The third limitation of *in vivo* NMR is the difficulty in making accurate quantitative measurements. The only quantitative studies of drug metabolism carried out so far have concerned fluorine- or lithium-containing compounds with ^{19}F or ^7Li NMR. For quantitative determinations, signal areas are normalized relative to that of an external reference – a capillary or a sphere filled with a standard of known concentration and volume. Within a particular experiment this method can estimate the relative concentrations of metabolites with an accuracy of approximately 10%, deteriorating to around 40% for the estimation of absolute concentrations. The absolute concentration in human brain of fluorinated neuroleptics or lithium salts has been determined by performing an additional separate calibration experiment (immediately before and after each experiment) with a phantom of known concentration and volume placed in the position of the tissue. However, since the tissue volume is not readily measured and since the loading on the coil and hence the nutation angle are assumed to be the same for the phantom as for the tissue, the method tends to be rather inaccurate. Another method consists in using a calibrated internal standard such as tissue water.

Table 3 Advantages and drawbacks of *in vivo* NMR for drug metabolism studies

Advantages	Drawbacks
Measurement of drug and metabolites levels in target organ	Low sensitivity. Tissue concentration necessary for <i>in vivo</i> detection of a drug is 1–10 times that necessary <i>in vitro</i>
Can be used repetitively on the same patient	Only molecules with unrestricted mobility are visible Prolonged data acquisition may be required The observed signals may have various anatomical origins Poor resolution. Chemically similar compounds may not be readily distinguished Difficult in making accurate quantitative measurements

Some Recent Applications of NMR in Drug Metabolism Studies

Most of the ^{19}F NMR studies are related to anaesthetic, psychoactive and antineoplastic drugs. The distribution of anaesthetics in the brain and the pharmacokinetics of their elimination are still a subject of controversy. The feasibility of *in vivo* ^{19}F NMR studies of halothane in humans has been demonstrated. Resonances attributable to this compound were observed up to 90 min after withdrawal of the anaesthetic agent in eight patients.

Fluoxetine (Prozac[®]) is a widely used antidepressant drug. In patients receiving daily doses of 20 or 40 mg, brain concentration continued to increase well after the clinical

effects were evident (2 weeks), seemed to level off after approximately 6 to 10 months of treatment and was approximately 20 times the concentration in plasma. It thus appears that there is no correlation between brain concentration and clinical response. A combined *in vivo* and *in vitro* study on several patients showed that the single ^{19}F resonance observed *in vivo* contains, in roughly equal proportion, both the drug and its active metabolite (norfluoxetine) (**Figure 1**). The comparison of *in vivo* and *in vitro* quantifications (1–11 μg of fluoxetine + norfluoxetine per millilitre of tissue *in vivo* versus 12–19 $\mu\text{g ml}^{-1}$ of tissue in extracts) suggested that a substantial fraction of the drug and its metabolite is not visible *in vivo*.

Most of the ^{19}F NMR studies on fluorinated drugs have concerned 5-fluorouracil (FU). This drug is an ideal case for ^{19}F NMR studies for three reasons. High doses are administered to patients. The fluorine atom remains intact during biotransformation. Its metabolism, and more especially its catabolic pathway, leads to compounds that are structurally different from the parent compound. The ^{19}F NMR signals are therefore displayed over a large spectral width with no peak overlap (except

for fluoronucleotides *in vivo*). The number of *in vitro* and *in vivo* ^{19}F NMR studies published reflects the contribution of the technique to the knowledge of FU metabolism. The following two examples emphasize the usefulness of ^{19}F NMR.

FU injected at high doses by continuous intravenous perfusion during 4 to 5 days provoked a cardiac toxicity. For commercial purposes, FU is solubilized in a solution of sodium hydroxide at two different pH (8.6 or 9.2). The ^{19}F NMR analysis of these solutions revealed the presence of about a hundred signals of fluorinated 'impurities', among which fluoroacetaldehyde and fluoromalonic acid semi-aldehyde were identified (**Figure 2**). These products come from the degradation of FU and are formed with time in the basic medium which is indispensable to the solubilization of this antitumour agent. These two compounds are highly cardiotoxic on the isolated perfused rabbit heart model since fluoroacetaldehyde is metabolized into fluoroacetate which is a violent cardiotoxic and neurotoxic poison. The degree of cardiotoxicity of FU commercial solutions, tested on the isolated perfused rabbit heart model, is a function of

Figure 1 The ^{19}F NMR spectra (a) from the head of a patient on 20 mg per day of fluoxetine for 1 month, (b) of the extract of a small section of temporal cortex from a deceased patient on 40 mg per day of fluoxetine for 19 weeks. F = fluoxetine, NF = norfluoxetine. Adapted from Komoroski, et al. (1994) *In vivo* ^{19}F spin relaxation and localized spectroscopy of fluoxetine in human brain. *Magnetic Resonance in Medicine* 31: 204–211, with permission of Williams and Wilkins.

Figure 2 The ^{19}F NMR spectrum of a commercial solution of 5-fluorouracil (pH 9.2). F^- , fluoride ion; FU, 5-fluorouracil; FMSAld, fluoromalonic acid semi-aldehyde; Facet, fluoroacetaldehyde.

the pH of the solution, and the preparations at pH 9.2 are less cardiotoxic than the preparations at pH 8.6. Nevertheless, the non-negligible frequency of cardiotoxic accidents observed after injection of the commercial solutions at pH 9.2 was too significant to be explained by the levels of fluoroacetaldehyde and fluoromalonic acid semi-aldehyde found in these preparations. The possibility of an eventual metabolism of FU itself into fluoroacetate has thus been explored. It has long been postulated, without ever being demonstrated, that the main catabolite of FU, α -fluoro- β -alanine, could be transformed into fluoroacetate. Using *in vitro* ^{19}F NMR and the isolated perfused rat liver model, it was found that the last catabolite of FU is not α -fluoro- β -alanine. The metabolism continues and leads to two new catabolites, fluoroacetate and fluoromalonic acid semi-alcohol (**Figure 3**). The conclusion of this study was twofold. To limit the cardiotoxicity of FU, it would be better to use in clinical treatments a new dosing form of FU which is devoid of degradation products (lyophilized material for example). However, to suppress this toxicity it would

Figure 3 The ^{19}F NMR spectrum of a perfusate of bodyweight (concentrated 20-fold by lyophilization) from an isolated perfused rat liver treated with 5-fluorouracil at a dose of 45 mg per kg b.w. for 3 h. F^- , fluoride ion; FUR, 5-fluorouridine; FU, 5-fluorouracil; FBAL, α -fluoro- β -alanine; CFBAL, N-carboxy- α -fluoro- β -alanine; FBAL[R]-gluc α , FBAL[R]-gluc β , adducts of α -fluoro- β -alanine with α -glucose or β -glucose; FMSAld, fluoromalonic acid semi-alcohol; FAC, fluoroacetate.

be necessary to act on the degradation pathway of FU by blocking it before the formation of α -fluoro- β -alanine.

In vivo ^{19}F NMR has been used to monitor FU metabolism in the liver metastases of colorectal cancer patients. The patients were treated with a continuous low dose intravenous infusion of FU until the point of refractory disease, at which time interferon- α was added with the objective of modulating FU activity. **Figure 4** shows the spectra obtained in a 1.5 T whole body spectrometer with a 16 cm diameter surface coil positioned over hepatic metastases of a patient treated with 300 mg of FU $\text{m}^{-2}\text{day}^{-1}$. The first NMR scan (**Figure 4a**) was performed after 1 week of FU infusion. A large signal of catabolite (α -fluoro- β -alanine) and a small resonance from FU were observed. The patient went on to have an objective partial response but later developed progressive disease. At this time (**Figure 4b**), the FU peak had disappeared and the catabolite signal had reduced. The next scan (**Figure 4c**), after a week on interferon- α , showed a new anabolite peak. A week later, the last scan (**Figure 4d**) showed FU and catabolite signals. At this stage the patient had a symptom and tumour marker response and stabilization of tumour size.

The ^1H NMR spectrum of a human urine sample from a volunteer who had ingested the anti-inflammatory drug flurbiprofen is shown in **Figure 5a**. The complexity of the spectrum precluded any detailed structural or quantitative analysis. For example, the ability to discern resonances from the aromatic protons of flurbiprofen

metabolites is severely limited. However, a stopped-flow HPLC-NMR experiment at 30.5 min afforded the ^1H spectrum shown in **Figure 5b** which corresponds to the two diastomeric forms of the β -D-glucuronic acid conjugate of 4'-hydroxyflurbiprofen. The resonances of the *para* substituted phenyl ring appear at 6.91 and 7.42 ppm and the other three aromatic resonances as a complex multiplet at 7.19 ppm. The β -D-glucuronic acid H1 proton appears as two resonances at 5.49 and 5.52 ppm. The remaining β -D-glucuronic acid resonances are located between 3.4 and 3.6 ppm. The methyl resonances of the propionic acid side chain of flurbiprofen are two doublets at 1.49 and 1.51 ppm. The two methine signals are observed at 3.94 ppm as overlapped multiplets. This example emphasizes the importance of HPLC coupled to NMR spectroscopy for the identification of drug metabolites.

^{13}C -labelled phenacetin has been used for the diagnosis of liver disease. In the urine of healthy subjects, the $-\text{OCH}_2-$ signal of phenacetin was higher than that of its metabolite, phenetidine, whereas in patients with acute hepatitis, the situation was the reverse (**Figure 6**). A return to the normal profile was observed during convalescence. The anticancer agent temozolomide labelled with ^{13}C was non-invasively detected in mice tumours by a selective cross-polarization transfer ^{13}C NMR method which has the advantage of higher sensitivity with lower power deposition. The resonance of temozolomide was observed but not the signal of its active metabolite, 5-(3-methyltriazene-1-yl)imidazole-4-carboxamide (**Figure 7**).

^{31}P NMR spectroscopy has been used to analyse biofluids from patients treated with the antineoplastic drug ifosfamide, widely used in the treatment of soft-tissue sarcomas and paediatric malignancies. Its metabolism is complex (Figure 8). The spectrum in Figure 9 emphasizes the wealth of information on drug metabolism that can be gained from *in vitro* studies. About 20 phosphorus-containing compounds were detected. In addition to the already known metabolites (unchanged ifosfamide, carboxyifosfamide, 2-dechloroethylifosfamide, 3-dechloroethylifosfamide, isophosphoramidate mustard, ketoifosfamide) eight other compounds were identified. Furthermore ^{31}P NMR spectroscopy has been used to detect and quantify ifosfamide *in vivo* in rat tumours. In addition to the resonances of the phosphorus-containing endogenous metabolites, only one broad signal could be detected for ifosfamide and, probably, also some of its metabolites. Carbogen breathing increased the amount of ifosfamide taken up by the tumour by 50% (Figure 10).

The concentration of Li in serum is not an adequate measure of Li efficacy. Localized spectroscopy that permits the measurement of Li in the brain may be a better approach of efficacy and neurotoxicity. Lithium was detected non-invasively *in vivo* in the brain and in the calf muscle of normal volunteers and of psychiatric patients.

Figure 8 Metabolic pathways of ifosfamide. Compounds ringed are phosphorylated metabolites that have been identified using ^{31}P NMR.

The lithium levels in both muscle and the brain rose more slowly than in serum. The concentration of Li in the brain is typically 0.1–0.6 mM. Therapeutic serum levels (ranging between 0.4 and 1.0 mM) are typically reached after 1 or 2 days of lithium treatment whereas clinical efficacy is not observed for several more days. The ^7Li NMR data strongly suggested that this delay may be due to the relatively slow accumulation of lithium in the brain (after 3–7 days of treatment). After the lithium treatment was stopped, the elimination half-time was slower in the brain (32–48 h) than in the serum or muscle (~24 h).

Conclusion

The increasing number of NMR studies of drug metabolism and pharmacokinetics testifies to the growing interest of the method. For *in vitro* studies (biofluids in particular), NMR can now be considered as complementary to, and even in some cases replacing, other analytical techniques such as chromatography. *In vivo* experimental and clinical applications of NMR are still at an early stage of development, and the techniques will need to be improved before localized spectra and accurate absolute quantification are routinely available.

Figure 9 The ^{31}P NMR spectrum of a urine sample from a patient treated with ifosfamide (3 g m^{-2} injected intravenously over 3 h). The urine sample was collected 8–16 h after the start of the infusion, frozen immediately after collection and concentrated 17-fold by lyophilization. Chemical shifts are related to external 85% H_3PO_4 . ALCOIF, alcofosfamide; CARBOXYIF, carboxyifosfamide; 2DEC1IF, 2-dechloroethylifosfamide; IF, ifosfamide; 3DEC1IF, 3-dechloroethylifosfamide; IPM, isophosphoramidate mustard; KETOIF, ketoifosfamide. Compounds ringed are phosphorylated metabolites that have been identified using ^{31}P NMR.

Figure 10 The ^{31}P NMR spectra of a GH3 prolactinoma. (a) Ifosfamide administered after 10 min breathing air. (b) Ifosfamide administered during tenth minute of breathing carbogen (CB). The spectra were acquired 15 min after intravenous ifosfamide. Peak assignments: 1, ifosfamide; 2, phosphomonoesters; 3, P_i ; 4, phosphodiester; 5, phosphocreatine; 6, γ -phosphate of NTP; 7, α -phosphate of NTP; 8, β -phosphate of NTP. Symbols

c	molar concentration
e_e	charge of electron
$E_T(30)$	solvent transition energy
f	oscillator strength
I	intensity
l	pathlength
m_e	mass of electron
M	transition dipole moment
ε	molar extinction coefficient

It seems appropriate to start an article on UV-visible absorption spectroscopy and dyes with a consideration of the fundamental processes underlying vision, for reasons which will presently become evident.

When electromagnetic radiation with wavelengths between 800 and 400 nm hits the human retina, a chain of events is initiated which eventually results in the excitation of the visual nerve and the perception of light or colour in the brain. The molecular basis for this process is the photoreceptor protein rhodopsin, which forms part of the membrane layers inside the cone and rod cells of the retina. The chromophore of rhodopsin, that is the coloured part of an otherwise colourless protein, is a highly unsaturated entity, 11-*cis*-retinal protonated Schiff base (**Scheme 1**). Through the action of light the Schiff base is transformed into an electronically excited state from which it returns, in a very fast reaction, to the ground state with the chromophore in the all-*trans* configuration (**Scheme 2**). Though there are many different visual pigments found in vertebrate eyes, with absorption maxima ranging from 415 nm in chicken to 575 nm in humans, nature uses the same chromophore, protonated retinal Schiff base, throughout. In addition, different pigments are found in the same species, a structural prerequisite for colour vision much like the light-sensitive layers of a colour film coated with different dyes.

Scheme 1

Protein

Scheme 2

How these spectral changes are brought about is not completely understood. The chromophore without the attached protein absorbs at 440 nm in ethanol. Embedding the chromophore in the protein changes the position of the absorption maximum, a consequence of the different environment. This environment consists of the amino acid residues of the protein, differing from species to species, which may be charged or uncharged. There are other counter-ions and water molecules which might induce solvatochromic effects. An amino acid placed in a particular position might induce deprotonation. For nature, this presents a perfect example of tuning the spectral characteristics of the visual pigment according to its needs. Conversely, one might consider the chromophore an extremely sensitive indicator of its molecular environment.

All molecular properties are a function of the environment. Often these changes are subtle and hidden

to the human eye. Sometimes, especially when dyes are involved, they are striking. Thus, dyes may be used as indicators of solvent polarity, of the pH or of the redox potential. Dyes will change their colours when they are adsorbed on surfaces or when they form complexes with other species or with themselves, that is when they aggregate. Spectral change, which is what we perceive as the colour change of a dye, always has a molecular basis. It provides yet another window for studying molecular structure and molecular interactions.

Spectral Characteristics of Dye Molecules

When light travels through a homogenous isotropic solution of an absorbing species, the fraction of light that is absorbed is proportional to the number of molecules in the light path according to the Beer–Lambert equation

$$\log_{10} \left(\frac{I_0}{I} \right) = \varepsilon \cdot c \cdot l$$

in which I_0 is the intensity of the incident and I of the emergent radiation. With the concentration c in moles per litre and the pathlength l in cm, the proportionality constant ε is the molar absorptivity or molar extinction coefficient. While ε is a measure of the *intensity* of the absorption, the wavelength λ at which the absorption occurs, or better its inverse, the wave number $\bar{\nu}$, is a measure of the *energy* which is absorbed, according to the well-known relation

$$E = \frac{hc}{\lambda} = hc\bar{\nu}$$

in which h is Planck's constant and c the speed of light. The range of UV-visible absorption extends from 800 to 200 nm (12 500 to 50 000 cm⁻¹) which corresponds to energies from ca. 35 to 145 kcal mol⁻¹ (1 kcal = 4.184 kJ). In molecules absorbing in this wavelength range these energies are sufficient to create short-lived electronically excited states. In such a state the electronic wave function does not correspond to the most stable arrangement of the electrons in the field of the nuclei; as a consequence the molecule returns, within 10⁻⁷ to 10⁻⁹ s, to the electronic ground state. Factors that affect the two states differently, for example chemical substitution, protonation or change of the solvent, will induce spectral shifts either to longer (bathochromic shift) or shorter (hypsochromic shift) wavelengths.

Empirical rules are widely employed to correlate chemical structure changes with spectral shifts. The spectra of short conjugated double bond systems can be predicted based on the topology and the presence of substituents (Woodward rules); linear free-energy

relationships have been developed to correlate substituent and spectral changes in closely related dye molecules. Other rules originate from basic quantum-mechanical principles, for example the linear relation between the absorption maxima of cyanine dyes and the length of the conjugated chain; the perturbation of a conjugated carbon chain by substituents of different electronegativity (perturbational molecular orbital theory); or the effects of steric crowding and, as a consequence, non-planar distortion of the molecule.

For a more quantitative description, theories may be applied which range from the purely π -electron, but highly successful PPP-theory and the semi-empirical all-valence electron theories such as CNDO/S and AM1 to *ab initio* methods. Only the latter allow the calculation of the energies without requiring recourse to experimental data. While it is possible today to calculate molecular ground state energies with an accuracy of a few kilocalories, depending on the size of the molecule and the computational effort expended, the uncertainty is much larger in the excited state. The *ab initio* calculation of absorption wavelengths which come within 50 nm of the experimental value must still be considered successful.

Calculated energies refer to the isolated molecule in the (dilute) gas phase. Every solvent will change these data to a degree. Solvent shifts can be striking when there is significant charge rearrangement between the ground and excited state. For computing these effects, one may allow specific interactions, for example through hydrogen bonds, of the dye with the solvent, though this approach is limited in the number of the solvent molecules that can be considered. In other approaches the dye molecule is specifically solvated and then embedded into a solvent continuum which in its response to the solute is treated as a polarizable dielectric.

A measure of the absorption intensity is the oscillator strength f , a dimensionless quantity which is obtained by integrating over the absorption band:

$$f = 4.315 \times 10^{-9} \int \varepsilon d\bar{\nu}$$

f can also be calculated from a theoretical quantity, the transition dipole moment M ,

$$f = \left(\frac{8\pi m_e \bar{\nu}}{3hc^2} \right) |M|^2$$

where m_e and e are, respectively, the mass and charge of the electron and $\bar{\nu}$ is the absorption wavenumber. M , a vector quantity, is a measure of the charge displacement caused by the electronic excitation. When the absorption can be attributed to the excitation of an electron from one molecular orbital to another with an energy sufficiently different from all other excitations of the molecule the magnitude and direction of M can be estimated

Figure 1 Highest occupied and lowest unoccupied molecular orbitals of azobenzene (schematic, a), their product, giving the transition density (b) and the resulting transition moment vector (c).

from multiplying the two orbitals which are involved in the excitation (Figure 1). This procedure gives atom-centered transition charge densities which are used to calculate the transition dipole moment. These 'back-of-an-envelope' calculations readily explain why the oscillator strength increases with the size of the chromophore, or why it is larger in the stretched conformation of a molecule than when it is coiled. The fixed orientation of M with respect to the molecular frame is also the physical basis for dichroism, that is the orientation dependence of the extinction coefficient of an ordered ensemble of dye molecules.

Electronic excitation in the UV-visible range is accompanied by changes in the vibrational and rotational state of the molecule as well. Since the spacing between rotational and vibrational levels is small relative to the spacing between electronic states, a typical UV-visual spectrum will appear as a band, or an envelope curve, of close-lying 'rovibronic states', the band shape being determined by the relative intensities of those states. Strong vibrations of the excited state may give rise to 'vibrational fine structure' of an absorption band, which may change as a function of the solvent and temperature.

positive solvatochromism. It is unreasonable to expect any macroscopic parameter, such as the dipole moment of a solvent or its refractive index, to correlate quantitatively with solvent effects which depend in addition on interactions at the molecular level. Therefore, empirical scales have been devised to correlate solvent polarity and spectral shifts.

One of the most popular and successful scales has been developed by Dimroth and Reichardt. It is based on the pyridinium-*N*-phenoxide betaine (Scheme 3), which exhibits one of the largest solvatochromic effects ever observed. The solvatochromism of this dye is negative since its ground state is considerably more polar than the excited state and is stabilized by polar solvents. Thus, in diphenylether the dye absorbs at 810 nm and appears blue-green, whereas in water the absorption is centred at 453 nm, giving an orange impression. The transition energy, expressed in kcal mol^{-1} , is the so-called $E_T(30)$ value of the solvent. $E_T(30)$ values have been determined and tabulated for more than 270 pure solvents and many different solvent mixtures. Protonation converts the dye (Scheme 3) into a phenol; as a consequence, $E_T(30)$ values cannot be measured for acidic solvents, such as carboxylic acids.

Dyes as Indicators of Solvent Polarity

Any solvent will change the wavelength, intensity and shape of an absorption band compared to the spectrum in the gas phase to a degree, a consequence of the different perturbation of the electronic ground and excited states of the solute by the solvent. The term '*solvatochromism*' has been coined to describe the change in position of an UV-visible absorption band due to a change in the polarity of the medium. A hypsochromic or blue shift with increasing solvent polarity is called negative solvatochromism, whereas a bathochromic or red shift is called

Scheme 3

Another solvent polarity scale, Kosower's Z -scale, is based on the highly solvent-dependent charge transfer absorption of the *para*-substituted pyridinium salt (**Scheme 4**). The ground state of this dye is best described as a highly polar tight ion-pair, whereas the less polar charge-transfer form is more important in the excited state. Thus, the solvatochromism of the pyridinium salt is negative, like Reichardt's dye. In fact, the $E_T(30)$ - and the Z -scale show a very good correlation, and similar anomalies with respect to theoretical polarity functions, which is not surprising because both use similar molecular models to 'measure' solvent polarity.

Scheme 4

For converting experimental transition energies $\bar{\nu}$ (in cm^{-1}) into $E_T(30)$ and Z -values, the following equation may be used:

$$E_T(30) = Z = bcN_A\bar{\nu} \\ = 2.8591 \times 10^{-3}\bar{\nu}$$

in which N_A is Avogadro's constant and both $E_T(30)$ and Z have the dimensions kcal mol^{-1} . The use of normalized, dimensionless values ' E_T^N ' has been recommended to avoid the non-SI unit. In this scale, water and trimethylsilane (TMS) are taken as reference solvents, with assigned values of E_T^N of 1.00 and 0.00, respectively.

$E_T(30)$ values show a good, often linear, correlation with a large number of other solvent sensitive processes, such as reaction rates and shifts of chemical equilibria. The betaine dye (**Scheme 3**) and specially designed derivatives are useful molecular probes in the study of micellar interfaces, microemulsions and phospholipid bilayers, of rigid rod-like isocyanide polymers, and the retention behaviour in reversed-phase chromatography. In addition to its solvatochromic behaviour, the dye is sensitive to temperature (thermosolvatochromism) and pressure changes (piezosolvatochromism) and also to the presence of electrolytes (halosolvatochromism).

Dyes as Indicators of Chemical Equilibria

For a dye to act as indicator of a chemical equilibrium, it has to meet two requirements; first, it must be able to participate in the reaction. That is, in an acid/base equilibrium the dye itself must have acidic or basic

properties; in a redox reaction, the dye must exist in different oxidation states; in a complexation reaction involving, for example metal ions, the dye must have complexing properties. Second, the different forms of the dye involved must absorb at different wavelengths, that is they must have different colours. Applications of dyes as indicators are of enormous importance in analytical chemistry.

One of the oldest applications of UV-visible spectroscopy is found in acid-base titrations and the determination of pK values. Several types of organic dyes are very sensitive to changes in the concentration of H_3O^+ (or OH^-) ions, for example azo dyes, phthaleines or triphenylmethane dyes. As a typical example, consider the protonation of methyl orange (**Scheme 5**), which occurs at a position on the *aza* bridge which allows the delocalization of the positive charge into the *p*-dimethylamino group. As a consequence, one of the aromatic rings becomes part of a cyanine type chromophore (eight π -electrons delocalized over seven atomic centres), with a concomitant bathochromic shift of the absorption spectrum and a colour change from yellow to red.

Scheme 5

The intense red, dianionic form of phenolphthalein (**Scheme 6**), which is stable in weakly basic solution, can be formulated as a resonance hybrid but is really another example of a cyanine-type chromophore, with oxygen instead of nitrogen. In acidic or strongly basic solutions, the negative charges are localized and the compound is colourless.

During titration, the sharp change of the pH near the end point is indicated by the visible colour change as the added indicator dye is converted from the basic into the acidic form (or vice versa). Since the end point of the titration does not necessarily coincide with neutrality of the solution, an indicator should be employed with a pK value that corresponds most closely to the pH of the end point. The concentrations (or better activities) of both the acidic and the basic form of the indicator are

then the same and true mixed colour is observed. For a determination of the indicator pK , the extinction coefficient ϵ of the dye is measured in buffered solutions at different pH values. According to the relationship

$$pK = pH + \frac{\epsilon - \epsilon_{\text{base}}}{\epsilon_{\text{acid}} - \epsilon}$$

the pK can be calculated from ϵ and the extinction coefficients of the indicator in strongly alkaline (ϵ_{base}) and strongly acidic solutions (ϵ_{acid}). All measurements should be performed in dilute solutions, and at wavelengths sufficiently distant from the isosbestic point where $\epsilon_{\text{base}} = \epsilon_{\text{acid}}$ and the extinction does not change with the pH.

Similar considerations apply to redox titrations, where the indicator dye should possess differently coloured oxidation states and a redox potential which is appropriate for the reaction to be studied. A large number of dyes are known which are suitable for this purpose. Ferroin (**Scheme 7**), a complex between iron(II) and phenanthroline with a deeply red colour, upon oxidation forms a pale blue iron(III) complex. Another redox indicator is diphenylamine (**Scheme 8**), which is colourless in the reduced state. It is oxidized in acidic solution irreversibly to diphenylbenzidine (**Scheme 9**) which can be further oxidized reversibly to the intensely coloured diphenylbenzidine violet (**Scheme 10**).

Comparable to an acid/base titration the end point of a redox titration is reached when the concentrations of

Scheme 6

Scheme 7

the reduced and the oxidized form of the dye are the same. The latter situation is somewhat more complex, however, because most redox reactions involve the exchange of protons, that is the equilibria are pH dependent.

In the determination of metal ions by ligand binding with ethylenediaminetetraacetic acid, EDTA, which has become known as complexometric or chelatometric titration, the end point may be indicated by so-called metal indicators. For this method to work, the metal to be titrated must form a less stable complex with the dye than with the complexing agent. Titration with the complexing agent binds all free metal in solution, until finally the dye is demetallated, too, which is manifest in the colour change. A very popular indicator is Eriochrome Black T (Scheme 11), which forms complexes with many different metals (the chromium complex is also used to dye protein and polyamide fibres). Between pH values of 7 and 11, the dye changes its colour from blue in the uncomplexed to red in the complexed form.

The end point of a titration may be indicated, besides the chemical transformation of a dye indicator, by physical processes, such as the adsorption of eosin from solution on the surface of a silver halide precipitate.

Dyes as Indicators of Molecular Environment

Any medium other than the vacuum will affect the absorption spectrum of a dye, through its bulk properties as a dielectric, which does not imply a fixed geometry or stoichiometry, and through specific interactions, such as electrostatic interaction, π - π stacking, or hydrogen bonding. The combination of any of these between a dye and an organic substrate may lead to the formation of an entity with a more or less well-defined supramolecular geometry, which exhibits characteristic spectral changes. As an example, consider the complex formed between *p*-nitrophenol and α -cyclodextrin (Figure 2). Cyclodextrins are water-soluble cyclic oligomers of amylose with a torus-like structure and a strongly hydrophobic inner lining. While they form complexes with many different guests, the complexation of dyes can be quantitatively followed by absorption spectroscopy. Usually, the low resolution of the spectra is not sufficient to develop a detailed structural model of these complexes, and other methods have to be used to implement the UV-visual spectroscopic data. The most accurate information is obtained from an analysis of X-ray data (Figure 2) which displays the orientation of the dye inside the cyclodextrin host. In contrast to the solid state the condition in solution is dynamic and more complex, since more species are involved, including the water molecules which are equilibrating between the solvent, the solute and the pore. However, the formation of a structured host-guest complex is supported by other spectroscopic methods, such as two-dimensional NMR spectroscopy.

The situation depicted above is typical for many cases where the complex formation between dyes and organic substrates is studied as a model for intermolecular interaction, the dye functioning at the same time as the complexed ligand and the indicator of this interaction.

Figure 2 Spectral change, A to B, on addition of α -cyclodextrin to an aqueous solution of *p*-nitrophenolate (left; after Saenger W (1980). *Angewandte Chemie* 92: 343). X-ray structure of the α -cyclodextrin-*p*-nitrophenol complex (right: after Harata K (1977) *Bulletin of the Chemical Society of Japan* 50: 1416).

The literature dealing with this topic is vast and ranges from histochemistry, where tissue is stained for diagnostic purposes, and biochemistry, where the complexation with dyes is used to model enzyme–ligand interactions and study possible binding sites, to organic polymers where dyes act as indicators of macromolecular conformations or of phase transitions.

Dyes, and their absorption changes, can be used to sense chirality and differentiate between two enantiomers ‘with the naked eye’, that is without the use of a polarimeter or any other device that measures optical activity. In principle every diastereomeric interaction between a chiral medium and the two enantiomers of a chiral dye must lead to different spectral characteristics. In practice, however, the effects are usually too small to be observed. The situation is different when diastereomeric supramolecular structures are involved. Thus, the colour of a phenol-based bowl-shaped agent (a ‘calixarene’) with two indophenol chromophores and a chiral binaphthyl subunit (Figure 3) turns blue-violet when it forms a 1:1 complex with (*R*)-phenyl-glycinol, while the corresponding complex with the (*S*)-isomer has a much smaller association constant and exhibits mainly the spectrum of the uncomplexed chiral sensor, which is red. As a consequence, it is possible to detect chirality by simple visible inspection. Similarly, supramolecular structures involving different kinds of non-bonded interactions have been invoked to account for the ability of chiral phases to discriminate between enantiomers in chromatographic separation techniques.

For a study of the molecular microenvironment, but also as promising new optical materials in solar energy conversion, for dye lasers, as optical switches or in non-linear optics, silicate glasses doped with dye molecules have been prepared by the sol–gel method. The formation of the porous solid from the initially liquid organic solution has been followed by UV-visible spectroscopy, and the acid/base reaction of the dyes with the inorganic matrix has been studied. Solvatochromic dyes have been used to determine the $E_T(30)$ values of

Figure 3 Possible structures of diastereomeric complexes formed between the bowl-shaped chiral calixarene and an (*S*)- (left) and an (*R*)-configured aminoalcohol. The shaded entities at the bottom represent the indophenol chromophores, the ones on top, the binaphthyl unit. R is a phenyl group of the chiral amine (Reproduced with permission from Kubo Y, Hirota N, Maeda S, and Tokita S (1998) Naked-eye detectable chiral recognition using a chromogenic receptor. *Analytical Sciences: The International Journal of the Japan Society for Analytical Chemistry* 14: 183).

different sol–gel materials. One advantage of these so-called xerogels is the immobilization of the embedded dye in a rigid cage, which prevents aggregation processes which are typical for concentrated dye solutions (see next section). Another aspect is the increased photochemical stability and fluorescence efficiency of the dyes. For the development of biochemical sensors, whole enzymes have been encapsulated in xerogels and their activity shown by the formation of dyes inside the glass from coupled enzyme reactions.

Dyes as Indicators of Aggregation and Molecular Order

Dyes have a natural tendency to aggregate, a consequence of their typically flat geometries which allows for maximum contact when the aggregation takes place side by side, in a sandwich manner. The aggregation is affected by non-bonding interactions, including π – π stacking, and is supported by hydrophobic effects when the solvent-accessible molecular surface is reduced as a consequence of aggregation. Aggregation is promoted by increasing the dye concentration in a solution or lowering the temperature. It is one of the most common causes for deviation of a solution from the Beer–Lambert law. Often a change of the solvent from polar to less polar or vice versa will be sufficient to effect dye aggregation or deaggregation. Aggregates may form spontaneously in solution or in the presence of polyelectrolytes, such as polyphosphates, or biological macromolecules, which may influence or even control the formation of the aggregate. Aggregates may form on solid surfaces, such as

mica, or they may be assembled as monomolecular layers on glassy surfaces. Dye aggregates grown on the surface of silver halide grains absorb light of suitable wavelength leading to latent images in the halide; this so-called spectral sensitization is the basis for photography. Dyes tend to concentrate at liquid interfaces and interact with surfactants leading to distinct spectral changes. Finally, dyes may adjust to the highly ordered environment present in liquid crystals, an area of huge technical importance.

Conspicuous colour changes take place when dyes aggregate. The spectral shifts caused by aggregation can be to longer or shorter wavelengths relative to the monomeric dye absorption. When dyes dimerize, a splitting of the absorption band may be observed. Formation of trimers, tetramers or larger oligomers is accompanied by increasing spectral shifts. The limiting value corresponding to an aggregate of 'infinite' size is called a 'J-band' characteristic of a J-aggregate when lying on the long wavelength side of the monomer absorption; if it appears on the high-energy side, it is called an 'H-band' (Figure 4).

These spectral changes are the result of the individual dye molecules interacting with each other in the close contact of the aggregate. Theoretical models based on the Coulomb interaction of the transition moments have been put forward to correlate the spectral shifts with certain geometrical parameters of the aggregate. Thus the hypsochromic shift observed in H-aggregates results when the dye contacts are mainly side by side. A lateral shift of the dye molecules against each other or a stacking into a brickstone work arrangement will lead to the bathochromic shift of a J-aggregate. While the H-band is usually sharp and intense due to the high order of the aggregate, the J-band may appear broad and featureless due to the loose and more irregular structure, but exceptions are well documented.

For studying dyes adsorbed on solids by UV-visible spectroscopy transparent solutions are necessary. There

are many inorganic colloids suitable for this purpose, such as silicas, charcoal, clays, zeolites or metal oxides, but also inorganic and organic polymers and even aggregates, such as micelles. Flocculation or aggregation of smaller particles may occur due to the adsorption of a charged organic dye on a polyelectrolyte which reduces the electrostatic repulsion by charge compensation.

The number of publications dealing with this topic is increasing rapidly. For studying the interaction of dyes with an enzyme the adsorption on solid surfaces with different binding characteristics may serve as a model. In this case the dyes are used in their classical role as indicators. Dyes are well suited for this purpose because of their strong tendency towards chemi- and physisorption. When the UV-visible properties of the adsorbed species change sufficiently the immediate comparison with dye molecules dissolved in a homogeneous solution is possible. Also, dynamic aspects of the adsorption of molecules on these surfaces can be examined by electronic absorption techniques.

The colour change accompanying the self-aggregation of dyes on solid surfaces is called metachromasy. Other properties of adsorbed dyes can also change allowing new or improved applications, such as enhanced stability against environmental effects such as oxygen or water or higher quantum yields for a photochemical conversion. New technologies are developing based on such processes. Solar energy conversion in photovoltaic cells, where charge carriers are generated by photoexcitation of dyes deposited on titanium dioxide surfaces, is a good example.

Complex equilibria between the dye and its surroundings may take place in heterogenous liquid mixtures, involving self-association, binding with ionic surfactants, micellar aggregation and micellar solubilization. These equilibria are concentration and temperature dependent, and involve entities with sometimes unspecific spectroscopic properties which leave plenty of room for discussion. Still, much can be learned from studying how dyes distribute in heterogenous systems since these can serve as models for the biodistribution of drugs in tissues and membranes and their behaviour at the lipophilic barrier. Also, the photosensitizing properties of a dye may increase when brought into a lipophilic environment.

H-aggregation of methyl orange has been postulated to account for the hypsochromic shift of the dye in a water-in-oil microemulsion, with the dye molecules in a parallel orientation at the interface between the water and the oil phase. The observation of salt-induced strongly red-shifted J-bands in aqueous solutions of Rose Bengal, an anionic xanthene dye, in the presence of zwitterionic surfactants was explained on the basis of head-to-tail aggregates of the dye molecules in novel premicellar aggregates.

Figure 4 Stacking of dye molecules (with transition moment vectors) which leads to a J-aggregate with red-shifted absorption relative to the monomer (left) and to an H-aggregate with blue-shifted absorption (right).

Highly ordered phases, so-called liquid crystals, are formed by a variety of rod-like, rigid dipolar organic molecules. Liquid crystals are also called the fourth state of matter since they combine the long-range order of a crystalline solid with the fluidity of a liquid. When a dye is dissolved in a liquid crystal the molecules will form ordered aggregates, with their long axes preferentially aligned with the liquid crystal molecules. These crystals are dichroic, that is they have different absorptivities for light polarized parallel and perpendicular to that axis, from which the orientation of the transition moment vector relative to the molecular framework can be determined.

The dichroism is the physical basis for the use of dyes in LCDs or liquid crystal displays: a small amount (0.1–1%) of the dichroic dye (the ‘guest’) is dissolved in a nematic or cholesteric liquid crystal (the ‘host’). Different orientations of the dye aggregates are achieved by application of an electric field through transparent electrodes. The dye will, for example align with its long axis parallel to the long axis of a nematic liquid crystal. If this solution is aligned in a parallel mode of the electrodes

and has a positive dielectric anisotropy, the cell will be coloured in the off position, when the dye absorbs strongly, and become colourless upon application of an electric field, when the alignment is changed.

k	wave vector
n_λ	refractive index at wavelength λ
p	photon momentum
S	spin
t	time
λ	wavelength
ν	frequency
$\bar{\nu}$	wavenumber
ω	circular frequency

Electromagnetic radiation is the technical term for light; not just visible light, but any light, ranging right

through from radio frequencies to gamma rays. As the name suggests, light of all kinds is radiated through conjoined electric and magnetic fields, as shown by Maxwell in the mid-nineteenth century. To fully appreciate the nature of electromagnetic radiation, however, we first have to consider both its wave-like and photonic aspects.

Waves and Photons

In the case of monochromatic (single-frequency) radiation, light propagates as a wave with a well-defined repeat or wavelength λ (Figure 1). Travelling at the speed of light, c , these waves oscillate at a characteristic frequency ν given by c/λ . The electric field, the magnetic field and the direction of propagation are mutually perpendicular, and for convenience may be chosen to define a set of Cartesian axes (x, y, z), respectively. With propagation in the z direction, the electric field vector points in the x direction and oscillates in the xz plane:

$$E(z, t) = E_0 \sin(kz - \omega t) \quad [1]$$

Figure 1 Oscillating electric field E and magnetic field B associated with monochromatic radiation.

where E_0 is the field amplitude and where also for conciseness we introduce $k = 2\pi/\lambda$ and $\omega = ck = 2\pi\nu$. The magnetic field vector accordingly points in the y direction and oscillates in the yz plane:

$$B(z, t) = B_0 \sin(kz - \omega t) \quad [2]$$

with amplitude B_0 . Given that the electric and magnetic fields oscillate in phase and in mutually perpendicular planes, eqns [1] and [2] together satisfy Maxwell's equations provided the amplitudes are related by $E_0 = cB_0$. In fact most spectroscopy involves the interaction of matter with the electric rather than the magnetic field of the radiation, because of its stronger coupling – usually by a factor of a thousand or more – with atomic and molecular charge distributions.

The speed of travel of an electromagnetic wave as described above can be understood in terms of the motion of any part of the waveform, such as the crest. The interval Δt between the arrival of two successive crests at any given point is given by $\omega\Delta t = 2\pi$, while at any time their spatial separation Δz also satisfies $k\Delta z = 2\pi$. So the speed of propagation $\Delta z/\Delta t = \omega/k = c$, which *in vacuo* takes the value $c_0 = 2.9979 \times 10^8 \text{ m s}^{-1}$.

On the radiation travelling through any substance, the electronic influence of the atoms or molecules traversed by the light reduces the propagation speed to a value less than c_0 ; then one obtains $c = c_0/n_\lambda$ where n_λ is the refractive index of the medium for wavelength λ ; accordingly, $k = 2\pi n_\lambda/\lambda$. The significance of the refractive correction is greatest in the solid or liquid phase, especially at wavelengths close to an optical absorption band of the medium.

A fundamental paradox in the nature of electromagnetic radiation, to some extent apparent even in the earliest scientific studies by Newton and others, is that it exhibits not just wave-like but also particle-like (corpuscular) properties, and both prove to be of key importance in spectroscopy. In particular, it is only through the association of discrete units of energy with electromagnetic radiation of any given frequency that we can properly understand atomic and molecular transitions and the appearance of spectra.

In the modern quantum representation of light developed by Planck, Einstein, Dirac and others, we now understand the twin wave and particle attributes through a description in terms of *photons* (a term in fact first introduced by the thermodynamicist Lewis). As such, electromagnetic radiation of a given frequency ν is seen to propagate as discrete units of energy $E = h\nu$, where h is the Planck constant.

With the key concepts in place, we can now take a look at some of the more detailed aspects of electromagnetic radiation in two stages — first by more fully enumerating the properties of photons in general terms,

and then by examining those more specific features that relate to particular wavelength or frequency regions of the electromagnetic spectrum.

Photon Properties

Mass

Photons are elementary particles with zero rest mass – necessarily so, since, from special relativity theory, no particle with a finite mass can move at the speed of light.

Velocity

The speed of light is normally quoted as speed *in vacuo*, c_0 , with refractive corrections applied as appropriate; the free propagation of any photon also has a well-defined direction, usually denoted by the unit vector $\hat{k}$.

Energy

Photon energy is linked to optical frequency ν through the relation $E = h\nu$ (where $h = 6.6261 \times 10^{-34} \text{ J s}$). Each photon essentially conveys an energy E from one piece of matter to another, for example from a television screen to a human retina.

Frequency

The optical frequency ν expresses the number of wave cycles per unit time. Also commonly used in quantum mechanics is the circular frequency $\omega = 2\pi\nu$ (radians per unit time), in terms of which the photon energy is $E = \hbar\omega$ where $\hbar = h/2\pi$. The lower the optical frequency, the more photons we have for a given amount of energy; and the larger the number of photons, the more their behaviour approaches that of a classical wave (this is one instance of the ‘large numbers’ hypothesis of quantum mechanics). It is for this reason that electromagnetic radiation becomes increasingly wave-like at low frequencies, and why we tend to think of radiofrequency and microwave radiation primarily in terms of waves rather than particles.

Wavelength

The wavelength λ of the electric and magnetic waves is given by $\lambda = c/\nu$. In spectroscopy, common reference is made to its inverse, the *wave number* $\bar{\nu} = 1/\lambda$, usually expressed in cm^{-1} .

Momentum

Each photon carries a linear momentum p , a vector quantity of magnitude $h/\lambda = \hbar k$ pointing in the direction of propagation. It is then convenient to define a *wave vector or propagation vector* $k = k\hat{k}$ such that $p = \hbar k$. Since the photon momentum is proportional to frequency,

photons of high frequency have high momenta and so exhibit the most particle-like behaviour. X-rays and gamma rays, for example, have many clearly ballistic properties not evident in electromagnetic radiation of lower frequencies.

Electromagnetic Fields

The electric and magnetic fields, E and B , respectively, associated with a photon are vector quantities oriented such that the unit vectors ($\hat{E}$, $\hat{B}$, $\hat{k}$) form a right-handed orthogonal set.

Polarization

For plane-polarized (also called linearly polarized) photons, the plane within which the electric field vector oscillates can sit at any angle to a reference plane containing the wave vector, as shown in **Figures 2a** and **2b**. Other polarization states are also possible: in the right- and left-handed circular polarizations depicted in **Figures 2c** and **2d**, the electric field vector sweeps

Figure 2 Polarization states: (a) and (b) plane; (c) and (d) circular.

out a helix about the direction of propagation. Elliptical polarization states are of an intermediate nature, between linear and circular. Together, the wave vector and polarization of a photon determine its *mode*.

Spin

Many of the key properties of photons as elementary particles relate to the fact that they have an intrinsic spin $S=1$, and so are classified as *bosons* (particles with integer spin as opposed to half-integer spin particles of matter such as electrons). As such, photons collectively display a behaviour properly described by a Bose–Einstein distribution. At simplest, this means that it is possible for their oscillating electromagnetic fields to keep in step as they propagate. Through this, coherent beams of highly monochromatic and unidirectional light can be produced; this is of course the basis for laser action.

Angular momentum

The intrinsic spin of each photon is associated with an angular momentum, a feature that plays an important role in the selection rules for many spectroscopic processes. Circularly polarized photons have the special property of quantum angular momentum: the two circular polarization states, left- and right-handed, respectively carry $+1$ or -1 unit of angular momentum, $\hbar$.

Regions of the Spectrum

We can now delineate the properties of the various spectral regions shown in **Figure 3**. Looking across the electromagnetic spectrum, it is immediately apparent that there is enormous difference in scale between the extremes of wavelength (or frequency), and it is not surprising to find that they encompass an enormous range of characteristics.

Gamma-Rays

This is a region of highly penetrating radiation with the highest optical frequencies (exceeding 3×10^{19} Hz), and an upper bound of 10 pm on the wavelength. Spectroscopy in this region primarily relates to nuclear decay process, as in the Mössbauer effect.

X-rays

This region encompasses both ‘hard’ X-rays (wavelengths down to 10 pm) and less penetrating ‘soft’ X-rays (wavelengths up to 10 nm) with optical frequencies lying between 3×10^{19} and 3×10^{16} Hz. With the capacity to produce ionization by electron detachment, photon energies in this region are often reported in electronvolts (eV), and run from around 10^5 eV down to

Figure 3 The electromagnetic spectrum.

100 eV ($1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$). X-ray absorption and fluorescence spectra as such mostly relate to atomic core electronic transitions.

Ultraviolet

With UV wavelengths running from 10 nm up to the violet end of the visible range at around 380 nm, this region is commonly divided at a wavelength of 200 nm into the ‘far-UV’ region (wavelengths below 200 nm, often referred to as ‘vacuum UV’ because oxygen absorbs here) and the near-UV (200–380 nm). With photon energies from 100 eV down to less than 10 eV – the latter being typical of the lowest atomic or molecular ionization energy – photoionization processes are associated with many of the techniques of ultraviolet spectroscopy. At the lower end of this region, photon energies are comparable with valence bond energies. As such they are commonly scaled by Avogadro’s number and reported in units of kJ mol^{-1} ; for example, the wavelength of 240 nm corresponds to 500 kJ mol^{-1} , a typical bond energy. One other form of division often applied to the near-UV region relates to its photobiological effects and applies principally to solar radiation; UV-A (320–380 nm) is the relatively safe region closest to the visible range; UV-B (280–320 nm) signifies radiation that can produce extensive tissue damage; UV-C radiation with wavelengths below 280 nm is potentially more damaging but is mostly filtered out by atmospheric gases that absorb here, the most important being ozone.

Visible

The visible range extends from approximately 380 nm (violet) to 780 nm (red) (**Table 1**). The precise divisions are a little arbitrary and depend on individual perceptions, but the wavelengths given in **Table 1** are a

Table 1 The visible spectrum

Colour	Wavelengths (nm)
Red	780–620
Orange	620–595
Yellow	595–575
Green	575–495
Blue	495–455
Violet	455–380

reasonable guide. Note that the link with perceived colour is not 1:1 – for example, light containing an equal mixture of red and green wavelengths appears yellow, although no yellow wavelengths are present. The visible range spans near enough an octave of frequencies and is a region in which photon energies are comparable with the bond energies of some of the weaker chemical bonds, running up from around 150 kJ mol^{-1} at the red end to over 300 kJ mol^{-1} at the other. Most of the spectroscopy in this range of wavelengths relates to electronic transitions unaccompanied by chemical change, and of course all absorption or fluorescence processes responsible for colour.

Infrared

This is another region commonly subdivided, in this case into the near IR (wavelengths running from the red end of the visible spectrum at 780 nm out to $2.5 \mu\text{m}$), the mid-IR (from 2.5 to $50 \mu\text{m}$) and the far IR ($50 \mu\text{m}$ to 1 mm). The absorption of near-IR radiation is commonly associated with the excitation of low-lying electronic excited states and overtones or combinations of molecular vibrations. In spectroscopic connections, the unqualified term ‘infrared’ generally refers to the mid-range, where spectral positions are usually cited by reference to wave-numbers $\bar{\nu} = 1/\lambda$. In the mid-IR range between 200 and

4000 cm^{-1} , it is principally vibrational transitions that accompany the absorption of radiation, with the corresponding nuclear motions less localized at the lower-wave number end of the scale. The far-IR region beyond relates mostly to low-frequency molecular vibrations and inversions, or rotations in small molecules.

Microwave

With wavelengths in the 1–100 mm range and frequencies on the GHz (10^9 Hz) scale, spectroscopy in the microwave region relates primarily to transitions involving molecular rotation, or others involving states of different electron spin orientation (electron spin resonance).

Radio

With radiation of wavelengths exceeding 100 mm we finally run into the radio wave region, where frequencies are commonly reported in MHz (10^6 Hz). Photon energies here are too small to lead to transitions associated with electronic or nuclear movement, but they can produce transitions between spin states (nuclear magnetic resonance).

As a caveat by way of conclusion, it should be pointed out that the nature of transitions studied by a particular spectroscopic technique is not always so obviously linked with a particular optical frequency or wavelength region if the elementary interaction involved in the spectroscopy entails more than one photon. For example, Raman spectroscopy allows molecular vibrational transitions to be studied with visible or ultraviolet light, while multiphoton absorption of IR radiation can lead to electronic excitations.

Gas-Phase Electron Diffraction

Applications

In this article, the scope of applications in structural chemistry is surveyed with some case studies as examples. Special attention is given to the combined application of electron diffraction and spectroscopic data for enhancing the scope and reliability of molecular structure determination.

Gas-phase electron diffraction has produced structural parameters of the molecules of thousands of substances during its eight-decade history. It has contributed to the understanding of the nature of the chemical bond and has been instrumental in establishing trends of structural variations in extended classes of compounds. It has also proved valuable for learning about the dynamics of molecules and their conformational characteristics. Interesting examples are ClF_3 , XeF_6 , and MnF_3 . These structures were determined correctly by gas-phase electron diffraction, and they were counterintuitive as regards the shapes that inspection of their structural formulas might have suggested. ClF_3 has a shape of C_{2v} symmetry instead of the more obvious trigonal planar or pyramidal. Its structure can be imagined in a trigonal bipyramidal frame, with two fluorine atoms in axial positions and one equatorial (Figure 1). The other two equatorial positions are occupied by two lone electron pairs of chlorine. XeF_6 has lower than octahedral symmetry. In both molecules, the lower symmetry of the molecules proves the stereochemical activity of the lone electron pair, supporting the utility of the VSEPR model. MnF_3 as a simple metal trihalide might have been expected to have a trigonal planar or pyramidal geometry. Its electron diffraction analysis, however, indicated that it has C_{2v} -symmetry structure, due to the ramifications of

Figure 1 Molecular model of ClF_3 .

the Jahn–Teller effect. Its radial distribution (more precisely the probability density distribution of intramolecular internuclear distances) shows that the three equal F–F distances split into two plus one, proving the distortion (Figure 2). For conformational equilibria, ethane-1,2-dithiol is an example.

In principle, there is hardly any molecular parameter about which there would not be information in the electron diffraction diagram, whereas in practice, important limitations may hinder their determination. The parameters for whose determination electron diffraction is an ideal method are the internal coordinates of the molecule, that is, bond lengths, bond angles, and angles of torsion. If a molecule has high symmetry, its geometry is defined by fewer parameters and can be determined with higher precision even if the molecule is fairly large. Thus, the molecule of adamantane is a 26-atom system, $\text{C}_{10}\text{H}_{16}$, but it has T_d symmetry (Figure 3), and information about its C–C bond length, 154.2 ± 0.2 pm, from electron diffraction, is among the most precise parameters in the literature. The C–C bond length in perfluoro-adamantane is 156.0 ± 0.3 pm, and the bond lengthening on fluorine substitution is determined reliably. The structure of the buckminsterfullerene molecule, C_{60} , could also be determined by electron diffraction in spite of its large size because of its high symmetry.

Another example of a very different but also fortunate target for gas-phase electron diffraction structure determination is the 36-atomic para-bis(trimethylsilyl) benzene, $p\text{-C}_6\text{H}_4[\text{Si}(\text{CH}_3)_3]_2$, whose radial distribution is

Figure 2 Radial distributions and molecular model of MnF_3 . The dashed line is calculated from the measured intensity data, and the continuous line is calculated for the shown C_{2v} -symmetry model. The positions of the different atom–atom distances in the molecule are indicated.

shown in **Figure 4**. The distribution is rich in features, which indicates that a wealth of structural information is obtainable for this molecule from electron diffraction. Thus, for example, the ipso angle in the benzene ring (the location of silicon substitution) was found to be $117.2^\circ \pm 0.3^\circ$, which is considerably different from the 120° of unsubstituted benzene. Information on a large series of substituted benzene derivatives made it possible to observe trends in the geometrical consequences of substitution, based solely on electron diffraction data. Incorporation of data from other methods enhances the possibilities and reliability of this information (see section Complementary Techniques).

Figure 3 Molecular model of adamantane.

There are many potential factors that may hinder the precise determination of structural parameters from electron diffraction and only a few are mentioned in this article. Even a small molecule may not be a fortunate target for gas-phase electron diffraction if it is asymmetrical. Molecules with similar interatomic distances are also less promising for obtaining precise information. Molecules with low-frequency, large-amplitude deformation motion present additional difficulties for yielding unambiguous structural information, even for small molecules. Examples are some of the alkaline earth dihalides, such as SrCl_2 and SrBr_2 , that have a very shallow bending potential with a small barrier at the linear configuration; these types of molecules are called quasilinear. During the past decades, high-precision experiments and powerful computational facilities have extended the possibilities of gas-phase electron diffraction. In many cases, it is still the technique of choice. In the section Complementary Techniques, some comments on other techniques are presented with the view of their potentials for joint application with gas-phase electron diffraction data in structure elucidation. This is, however, preceded by a brief survey of the physical meaning of the structural parameters whose consideration is mandatory before embarking on the combined application of data from different techniques.

Average Structures

The internuclear distances determined by electron diffraction refer primarily to the nuclear positions and are only slightly perturbed by the electron density

Figure 4 Radial distribution curves (stars: experimental; continuous line: calculated) and the molecular model for para-bis(trimethylsilyl)benzene. The positions of different atomic pair contributions are indicated.

distribution. The internuclear distance, r_a , in the expression of the molecular component of electron scattering intensities is an effective parameter (operational parameter), which has no rigorous physical meaning. However, it is related to one with well-defined physical content, the r_g thermal-average internuclear distance. To a good approximation, $r_g = r_a + l^2/r_a$, where l is the mean amplitude of parallel vibration (i.e., in the direction of the line connecting the two atomic nuclei). There are then the distances between average nuclear positions, r_α and r_α^0 , the former of which refers to thermal averaging and the latter to 0 K. The average internuclear distance, r_g , differs from the distance between average nuclear positions, r_α , in the consequences of perpendicular (i.e., to the line connecting the two atomic nuclei) vibrations. The consequences of bending vibrations of a symmetrical linear triatomic molecule on the instantaneous distance between the two end atoms are shown in **Figure 5(a)**. The same vibration is described by Cartesian displacements in **Figure 5(b)**. It can be deduced from both descriptions that the thermal-average bond angle is smaller than 180° . Thus, the symmetry of the thermal-average structure may well be lower than the symmetry of the equilibrium structure. With proper vibrational corrections, however, these discrepancies can be eliminated. It is noted that even in rather rigid molecules, where this effect is far from being strong, it has to be taken into account if geometrical parameters of different representations are compared or jointly applied, above a certain accuracy requirement.

An important distance type is the equilibrium distance, r_e , that corresponds to the hypothetical motionless molecule residing in the minimum position of the potential energy surface. This is the distance that is provided by quantum chemical calculations. The r_α^0 internuclear distance differs from the r_e equilibrium distance by the consequences of anharmonicity of the vibrations along the line connecting the two atomic nuclei. Owing to the mass dependence of anharmonicity, all

Figure 5 The consequences of bending vibrations of a symmetric linear triatomic molecule on the instantaneous distances between atoms. Description with (a) curvilinear and (b) Cartesian coordinates. In the former, the bond distance is constant and the end-to-end distance decreases; in the latter, the bond distance increases whereas the end-to-end distance remains constant.

average internuclear distances will be different for different isotopes of the participating atoms. The consequences of various vibrational effects are summarized in **Table 1**. Applying appropriate vibrational corrections, all distances can be derived from the internuclear distances determined directly from a gas-phase electron diffraction structure analysis.

In the expression of the molecular component of electron scattering intensities, the mean amplitudes of vibration figure for all internuclear distances. Usually they are not of primary interest in an electron diffraction structure determination, and it is useful to incorporate information about them from other sources. Such a source may be a normal-coordinate analysis utilizing vibrational frequencies and molecular force fields either from spectroscopic techniques or from quantum chemical computations. Molecular mechanics calculations may also be a source for the mean amplitudes of vibration to be used as initial parameters or assumed values in an electron diffraction structure analysis.

Complementary Techniques

High-resolution rotational spectroscopy, and most often the pure rotational spectra (microwave spectroscopy), is a complementary source of structural information for gaseous molecules in an electron diffraction structure analysis. Its geometrical findings usually appear in terms of operational parameters r_0 and r_s . The r_0 internuclear distance is obtained from the rotational constants and usually, though not always, refers to the ground vibrational state. It depends strongly on the isotopic composition and may considerably differ from the equilibrium distance. The r_s internuclear distance is determined from the isotopic substitution coordinates of the respective atoms. It depends only slightly on the isotopic composition and thus may only slightly differ from the equilibrium internuclear distance. However, neither r_0 nor r_s have rigorously defined physical meaning. Vibrational corrections may also be applied to the primary data from rotational spectroscopy, and consequently, internuclear distances between average nuclear positions may be obtained; they are labeled r_z and correspond to the r_α^0 distances from electron diffraction. They are very useful in the characterization of bond angles, but are less useful for describing bond lengths because they are averages projected onto the direction of the lines connecting equilibrium nuclear positions. An

Table 1 Representations of average structures

Effect on structure	r_g	r_α	r_α^0	r_e
Perpendicular vibrations	yes	no	no	no

Isotope	yes	yes	yes	no

excellent representation of bond length is the r_g distance, as it is a real distance averaged over all molecular vibrations. The most unambiguous representation of molecular geometry is in terms of the r_e equilibrium distances. The uncertainties in the determination of r_e parameters no longer refer merely to precision, but can be considered to characterize the accuracy of the structure determination.

If the electron diffraction structural parameters are converted into r_α^0 distances and the rotational constants from the microwave spectra (A_0 , B_0 , and C_0) into A_z , B_z , and C_z rotational constants, referring to the distances between average nuclear positions in the ground vibrational state, then the measurements from the two techniques can be used in a combined way in the structure refinement. The conversion can be carried out by means of a harmonic force field and normal-coordinate analysis. Note that although the conversion is done on the geometrical parameters for electron diffraction, it is done on the rotational constants for microwave spectroscopy. In a combined refinement, the quantity to be minimized may be, for example,

$$\sum_{k=1}^n [s_k M_k^E(s_k) - s_k M_k^T(s_k)]^2 W_k + \sum_{j=a,b,c} (I_j^E - I_j^T)^2 W_j$$

where M^E and M^T represent the experimental and calculated molecular intensities and I^E and I^T the experimental and calculated principal moments of inertia, respectively. The latter are calculated from the respective rotational constants. The choice of the relative weights W_k and W_j is a delicate matter for which no general formula is available. Depending on the data and the structural problem under investigation, various schemes have to be tested. Whereas the electron diffraction intensity measurements may number over a hundred, the introduction of three, or sometimes even fewer, pieces of data from high-resolution spectroscopy may eliminate the ambiguity of a structure determination and result in noticeable enhancement of accuracy. This is because the pattern of correlation among the parameters may be strikingly different for the two sets of observables. Thus, for example, for sulfone molecules, such as SO_2Cl_2 and SO_2F_2 , the tetrahedral sulfur bond configuration results in rather closely spaced nonbonded distances, which hinder their precise determination from electron diffraction, whereas their bond lengths can be determined with high precision. However, the distances O–O as well as Cl–Cl for SO_2Cl_2 or F–F for SO_2F_2 can be determined directly from the principal moments of inertia with no similar information on the bond lengths of these molecules from the microwave spectra. Even without vibrational corrections, the utilization of complementary information from the two techniques has great

importance. In such a case, however, the final refinements should be done by removing data from the other technique lest systematic errors be introduced by the uncorrected measurements.

The above-discussed example illustrates the point that a general scheme for combined application of different techniques could hardly be useful. Indeed, a very broad range of approaches may be followed when incorporating additional information in an electron diffraction structure analysis. The procedure may range from the use of some chemical experience in constructing models in the initial stages of the analysis to built-in calculated vibrational amplitudes from normal-coordinate analysis in the least-squares refinements to assuming differences of similar bond lengths or relative contributions of different conformers from other techniques. Quantum chemical calculations have played an increasing role in electron diffraction structure analysis in many ways. They can provide computed parameter differences for the least-squares refinement in case of closely spaced distances, vibrational frequencies, and force fields for normal-coordinate analysis to produce vibrational amplitudes, information on possible molecular models that correspond to the global minimum and low-energy local minima on the potential energy surface together with their energy differences and energy barriers, types and relative amounts of different conformers possibly present in the vapor based on their energy differences, and so on.

Vibrational frequencies, either from infrared or Raman spectroscopic measurements or from computation, may also be incorporated into the structure refinement; this has been especially useful for small molecules with large-amplitude vibrations. Besides other gas-phase experimental methods, liquid crystal NMR has also proven useful to combine with electron diffraction data. The inclusion of dipolar couplings from solution-phase NMR studies in the analysis increases the precision of the structure determination as has been shown for different benzene derivatives. Mass spectrometry has been very helpful in providing knowledge about the vapor composition and in the optimization of the experimental conditions. In case of complex vapor composition, computations are also an invaluable aid to the electron diffraction analysis. An example is chromium dichloride that has different oligomers in its vapor besides the monomer that, according to the computations, has a C_{2v} -symmetry structure due to the Renner–Teller effect. Utilizing the information from computations, the structure of the monomer as well as the oligomers could be determined from electron diffraction; without this additional information, this proved to be impossible. Molecules with different conformers present in their vapors can also be better studied with the approach of joint analysis and thus more parameters can be determined. Thus, enhanced amount of structural

information for conformers include their relative amounts and their temperature dependence, energy barriers, and the subtle geometrical differences between their structures.

Comparison with structural information from X-ray crystallography has also been instrumental. In detailed comparison, it has to be born in mind that X-ray diffraction yields distances between the centroids of the electron density distribution rather than internuclear distances, but they can well approximate the distances between average nuclear positions. Thus, the best comparison may be in terms of the r_x^0 structures. If the molecular structures of the same substance determined by gas-phase electron diffraction and X-ray crystallography show significant differences (i.e., beyond experimental uncertainties), those differences can be ascribed to the impact of intermolecular interactions in the crystal.

Today, by far, most gas-phase electron diffraction analyses are carried out in combination with other techniques. The most often applied additional method is quantum chemical calculations. Often, data from rotational and vibrational spectroscopy and from liquid crystal NMR are also incorporated in the joint analysis in order to get a deeper and more reliable insight into the structure of the molecule. Different structural techniques usually are sensitive to different characteristics of a molecule and may thus ideally complement each other,

and this is what makes the joint analysis valuable and the way of the future.

Gas-Phase Electron Diffraction

Theory and Methods

The eight-decade-old gas-phase electron diffraction technique of molecular structure determination was originally initiated in an industrial laboratory by the chemist Herman F. Mark and the physicist Raimund Wierl, who published a brief report in 1930. They determined the geometry of a series of simple molecules based on a visual evaluation of intensity distributions of the scattered electrons. Then, the technique was taken over by the California Institute of Technology and other academic laboratories, and Linus Pauling and Lawrence Brockway introduced a visually more appealing approach by producing the so-called radial distribution – a misnomer for the probability distribution function of the intramolecular interatomic distances. The technique distinguished itself by yielding direct information on molecular structure and has remained one of the principal experimental sources of such data.

Gas-phase electron diffraction is a source of internal coordinates of the molecular geometry, such as bond lengths, bond angles, and angles of torsion and of information related to molecular dynamics, such as mean amplitudes of vibration, conformational abundances (and thus energy patterns between conformers), and even barriers to internal rotation.

One of the roots of gas-phase electron diffraction is in the theory worked out for the diffraction of X-rays by randomly oriented rigid systems of electrons, where it was found that the interference effects do not cancel in the scattered intensity distribution. This is well demonstrated by the diffuse character of the interference patterns produced in a gas-phase electron diffraction experiment in **Figure 1**. Another of the roots of the technique is in Louis de Broglie's discovery about the wave nature of moving electrons. Ignoring the relativistic corrections (the higher the electron energy the poorer such an approximation is), $\lambda = h/mv$, where λ is the electron wavelength, h is the Planck constant, m is the electron mass, and v is the electron velocity.

Experiment

In a typical gas-phase electron diffraction experiment for molecular structure determination, a beam of fast electrons is scattered by a beam of vapor molecules. The electron beam is usually of energy in the range of 40–100 keV; and it needs to be monochromatic, that is, of very little scatter in energy. The relationship between the

electron wavelength and the potential U used for accelerating the electrons is $\lambda = h/(2meU)^{1/2}$, where e is the elementary charge. The pressure in the vapor beam is in the order of several tens of mmHg. Molecules having atoms with higher atomic numbers are stronger scatterers than molecules consisting of light atoms. The sample needs to be pure, but impurities may hinder the analysis in varying degrees depending on their ability to scatter electrons and on the distribution of their internuclear distances. Impurities with very different atoms and interatomic distances than the principal molecule disturb the emerging results less than those whose scattering is similar to the main target of the experiment. The higher the molecular symmetry the more reliable is the structure determination. Here, the complementary nature of gas-phase electron diffraction and microwave spectroscopy can be sensed, because the latter is disadvantageous for molecules with no electric dipole moment.

At the beginning of the applications of gas-phase electron diffraction, the photographs of the diffraction patterns were evaluated visually, utilizing the exaggerating ability of the naked eye in distinguishing maximum and minimum interferences on the steeply falling background of the atomic electron scattering. Eventually, the introduction of a technical device, the so-called rotating sector, made a more quantitative determination of the molecular

Figure 1 Gas-phase electron diffraction pattern of adamantane, $C_{10}H_{16}$.

component of the intensity distribution possible. This greatly enhanced the scope and precision of structure determinations. Lately, in addition to the time-honored photographic techniques, digital techniques have also been employed. The scheme of a traditional experiment is presented in **Figure 2**. In some special experiments, mass spectrometric control has been added to the electron diffraction setup, which assists the determination and even optimization of vapor composition for establishing the best conditions for the scattering experiment. The scheme of such a combined experiment is presented in **Figure 3**.

Theory

A few expressions are presented to help the understanding of the origin of physical information derived from the experiment without demonstrating the way of arriving at them. First, the electron scattering intensity

Figure 2 Principle of the gas-phase electron diffraction experiment.

distribution as a result of electron scattering by randomly oriented rigid molecules is given as a function of a scattering angle variable, s , defined as $s = (4\pi/\lambda) \sin(\theta/2)$, where λ is the electron wavelength and θ is the scattering angle. Only elastic scattering is considered.

The electron scattering intensity distribution for rigid molecules is given by

$$I(s) = KI_0 R^{-2} \sum_{i=1}^N \sum_{j=1}^N f_i(s) f_j^*(s) \sin(sr_{ij}) / sr_{ij}$$

Here, I_0 is the intensity of the incident electron beam, R is the distance between the scattering center and the observation point, K is a constant that can be expressed in terms of fundamental constants, N is the number of atoms in the molecule $f_i(s)$ and $f_j^*(s)$ are the scattering amplitudes of the i th and j th atom, respectively, and r_{ij} is the internuclear distance. This expression contains the scattering of electrons by the individual atoms in the molecule ($i=j$) as well as the scattering of electrons by atomic pairs ($i \neq j$), which is relevant to molecular structure. Accordingly, $I(s)$ may be considered as consisting of two components; one is $I_a(s)$, the atomic component, and the other, $I_m(s)$, is the molecular component. Thus,

$$I(s) = I_a(s) + I_m(s)$$

and

$$I_a(s) = KI_0 R^{-2} \sum_{i=1}^N |f_i(s)|^2$$

and

$$I_m(s) = KI_0 R^{-2} \sum_{i=1}^N \sum_{j=1, (i \neq j)}^N f_i(s) f_j^*(s) \sin(sr_{ij}) / sr_{ij}$$

Figure 3 Scheme of a combined gas-phase electron diffraction/quadrupole mass spectrometric experiment.

Atomic scattering amplitudes, $f_i(s)$, may be introduced at different levels of approximation (the asterisk denotes complex conjugate). A rough approximation is to assume $f_i(s) = Z_i$ where Z_i is the atomic number of the i th atom. In this case, the scattering by the electron cloud, which is especially important at low scattering angles, is ignored. A more adequate expression is of the form

$$f_i(s) = Z_i - F_i(s)$$

where $F_i(s)$ is the contribution of the electron density distribution to the scattering amplitude. This expression is valid under the assumption of a weak scattering potential, so the electron wave encountering each volume element within the molecule is the unperturbed, incident wave. This is called the *kinematic approximation*, known as the *first Born approximation* when applied to electron diffraction.

However, scattering potentials are mostly not weak, and an electron wave undergoes a significant phase shift as it propagates through the field of the scatterer. The phase shift increases with increasing atomic number and increasing scattering angle. The atomic scattering amplitudes used in modern structural work take the phase shift into account and are of the form

$$f_i(s) = |f_i(s)| \exp[\eta_i(s)]$$

where $|f_i(s)|$ is the modulus of the amplitude and $\eta_i(s)$ is the phase angle in radians. If these complex scattering amplitudes are used, the expression for the molecular intensity is written as

$$I_m(s) = KI_0 R^{-2} \sum_{i=1}^N \sum_{\substack{j=1 \\ (i \neq j)}}^N g_{ij}(s) \sin(sr_{ij})/sr_{ij}$$

where

$$g_{ij}(s) = |f_i(s)| |f_j(s)| \cos[\eta_i(s) - \eta_j(s)]$$

This formalism (*quasi-kinematic approximation*) corresponds to the introduction of multiple scattering effects within the same atom (*intraatomic multiple scattering*). If the molecule is composed of light atoms, or atoms not differing too much in atomic number, then the phases $\eta_i(s)$ are similar and the diffracted intensity is not much different from that expected from the kinematic approximation. If one or more atoms are substantially heavier than the others, the deviation from the kinematic theory cannot be ignored. Using the kinematic theory in structure analysis then introduces distortions in the geometry of the molecule. A classic example is rhenium hexafluoride, ReF_6 , where the peak corresponding to the Re–F distance is split in the radial distribution. Using the quasi-kinematic approximation explains the splitting of the Re–F peak, and leads to the expected, regular

octahedral geometry. The treatment of multiple scattering by different atoms in the same molecule (*interatomic multiple scattering*) requires a more sophisticated approach.

However, it is stressed that molecules are not rigid bodies, and the vibrational motions may cause variations in internuclear distances of several picometers. The molecular component of the electron scattering intensity for the vibrating molecule is

$$I_m(s) = KI_0 R^{-2} \sum_{i=1}^N \sum_{\substack{j=1 \\ (i \neq j)}}^N g_{ij}(s) \exp(-l_{ij}^2 s^2 / 2) \sin(sr_{ij})/sr_{ij}$$

where l_{ij} is the mean vibrational amplitude along the line connecting the two nuclei, and r_{ij} is now an effective internuclear distance. This internuclear distance is usually denoted as r_a , and is related to the vibrationally averaged internuclear distance at the temperature of the electron diffraction experiment, r_g , by the expression

$$r_a \approx r_g - l^2 / r_a$$

to a good approximation. If the vibration is anharmonic, the term $\sin(sr_{ij})$ in the above equation should be replaced by $\sin[s(r_{ij} - \kappa_{ij}s^2)]$, where κ_{ij} is an asymmetry parameter related to the a constant of the Morse equation. In favorable cases, κ_{ij} values can be determined from the electron diffraction data.

Structure Analysis

The experiment yields the total electron scattering intensity distribution, and it is a crucial step to extract the molecular component from it. In addition to the atomic component, there is also an inelastic scattering part of the intensity that is to be eliminated together with the consequences of extraneous scattering, depending on the particular construction of the experiment. All these can be considered together as making up the experimental background (inelastic + atomic + extraneous), $I_b(s)$, and $I_m(s) = I(s) - I_b(s)$. The molecular contribution to the electron diffraction intensities – in short, molecular intensities – is the experimental data on which the determination of structural parameters is based, more often than not, using a least-squares refinement technique. Fourier transformation of the molecular intensities yields the so-called radial distribution, $f(r)$ (a misnomer, because in reality it is related to the probability density distribution of the intramolecular internuclear distances). The molecular model, total intensities, molecular intensities, and radial distribution for tetramethylsilane are displayed in **Figures 4–7** using a simple case study from our research group.

Figures 6 and **7** show not only the experimental distributions but also the distributions calculated for the

Figure 4 Molecular model of tetramethylsilane.

Figure 7 Radial distributions for tetramethylsilane. The vertical scale is arbitrary. The continuous line is calculated for a model; the dots are calculated from the measured intensity data.

best model of tetramethylsilane, which is characterized by the following bond lengths and bond angles, Si–C 187.7(4) pm, Si–H 111.0(3) pm, and Si–C–H 111.0(2) pm as well as T_d symmetry and a staggered methyl conformation. The bond lengths and the bond angles here are so-called average parameters, see more on this in another entry of this encyclopedia. The radial distribution is convenient to visually inspect the validity of a model and to read off some principal internuclear distances, but the quantitative determination of all the parameters is done on the basis of the molecular intensities. The refinement of parameters usually starts from an initial set of parameters. The expression of the molecular intensities is a nonlinear relationship; a good choice of the initial parameters will ensure that the calculation reaches the global rather than a local minimum.

Tetramethylsilane is a fortunate subject for electron diffraction, because of its high symmetry. Only a few parameters determine its geometry and almost all of their contributions are well resolved. Less symmetrical molecules usually have radial distributions on which the individual contributions are not so easily discernible. Even in such cases, the least-squares refinement of the parameters based on the molecular intensities may yield satisfactory results. For increasing molecular complexity, decreasing precision of the parameters may be the price to pay. In any case, the gas-phase data yield – in the usual terminology of X-ray crystallography – a one-dimensional Patterson function, which indicates the limitations of the technique toward more complex structures. It is desirable to learn as much as possible about the composition of the vapor sample used in the experiment from independent sources. The vapor composition may yet be another unknown to be determined in the analysis.

In case of a conformational equilibrium of, say, two conformers of the same molecule the analysis may be more difficult but the results may be more rewarding at the same time. The analysis of ethane-1,2-dithiol at the temperature of 343 K revealed the presence of 62%

Figure 8 Ethane-1,2-dithiol has a mixture of the anti (a) and gauche (g) forms at 343 K, with respect to the S–C–C–S framework. The bottom curve was calculated from experimental data.

of the anti form (a) and 38% of the gauche form (g) as far as the S–C–C–S framework was concerned. The radial distributions calculated for a set of models and the experimental distribution in **Figure 8** serve as illustration.

In the best cases, the gas-phase electron diffraction technique yields precisions of a few tenths of a picometer

for bond lengths, a few tenths of a degree for bond angles, and a few degrees for angles of torsion. The precision and generally, the reliability of structure determination may be enhanced considerably by concerted and combined application of electron diffraction experiments with spectroscopic measurements and quantum chemical calculations. In such cases, however, the question of accuracy has to be carefully considered as the physical meaning of structural information from different techniques varies. The combined application of techniques and the physical meaning of parameters are among the aspects discussed in another entry of this encyclopedia.

Atomic absorption spectroscopy and atomic emission spectroscopy have found application in many areas of materials science. The electronics industry requires materials of high purity and hence there is a need to monitor trace impurity levels in materials used for electronic components. As a consequence, various techniques of atomic spectroscopy have been applied to the analysis of materials used in the manufacture of electronic components. A number of recent studies are listed in the Further reading section and these therefore provide an entry point to the scientific literature. The reader should also consult other articles in this encyclopedia for related topics.

For example, the analysis of electronic grade silicon has been studied using atomic emission spectroscopy from inductively coupled plasma and the level of aluminium and phosphorus in such material has also been determined using an indirect atomic absorption method. The growth of europium on palladium surfaces has also been investigated using atomic emission spectroscopy.

The use of inductively coupled plasma–atomic emission spectroscopy (ICP-AES) has been applied to the analysis of traces of certain rare earth metals in highly pure rare earth matrices and to the levels of approximately 25 impurities in sintered electronic ceramics.

The impurity levels and profiles from the surface into the bulk sample have been probed using a combination of secondary-ion mass spectrometry and electrothermal atomic absorption spectroscopy in composite materials such as CdZnTe.

The environmental impacts of impurities and by-products associated with nano-manufacturing processes have been addressed in an initial study. The composition and consequent aquatic toxicity of fullerene (C-60) and metallofullerene waste solids has been investigated. Scanning electron microscopy with energy dispersive X-ray spectroscopy (SEM-EDX) and inductively coupled plasma mass spectroscopy (ICP-MS) were used to characterize the metals composition of the solid test materials and of aqueous leachates prepared by mixing test materials with waters of varying pH, hardness, and

salinity. The aquatic toxicity of the leachates was determined using U.S. Environmental Protection Agency recommended aquatic bioassay protocols. Metals associated with the solid test materials became mobilized and reached concentrations sufficient to induce toxicity in model test species. These results demonstrated the need for a global review of nano-manufacturing wastes and low-purity products.

Electrospray Ionization in Mass Spectrometry

Keqi Tang, Jason S Page, Ryan T Kelly, and Ioan Marginean, Biological Sciences Division, Pacific Northwest National Laboratory, Richland, WA, USA

Published by Elsevier Ltd.

Introduction

Electrospray is the product of a special liquid atomization process that relies on the electrostatic force to break a liquid of finite conductivity into a plume of highly charged fine droplets. Electrospray ionization (ESI) describes an ionization process in which gas-phase ions are generated from these highly charged droplets. Since the unique feature of ESI in generating multiply charged ions for large molecules and its 'soft' nature for gas-phase ions to retain their liquid phase conformation were discovered in the 1980s by Fenn et al. at Yale University, ESI has revolutionized mass spectrometry (MS) and become a preferred ionization technique for MS in a broad range of chemical and biological applications.

The implementation of the ESI source on a mass spectrometer is achieved by using an ESI–MS interface. As illustrated in **Figure 1**, the electrospray emitter in the atmospheric pressure environment is typically mounted on a translation stage to allow fine adjustment of its position with respect to the MS inlet, which is either a heated capillary as shown in **Figure 1** or a small orifice. For direct infusion analysis, a microsyringe, driven by a syringe pump, can be used to feed sample solution to the ESI emitter at a controlled flow rate. The ESI emitter is connected to the microsyringe by using a fused silica capillary and a metal union. Alternatively, the syringe pump can be replaced by a liquid chromatography (LC) system for sample separation before ESI–MS analysis. The necessary voltage (1–3 kV) for electrospray operation is supplied by connecting a high-voltage DC power supply to the metal union. The charged droplets/solvent clusters in the electrospray are desolvated in the heated

capillary. The fully desolvated analyte ions are transmitted through a skimmer, positioned a short distance downstream of the capillary/orifice exit, into the MS analyzer for their mass-to-charge (m/z) ratio measurements.

The sensitivity of ESI–MS is largely determined by the efficiency of producing gas-phase ions from analyte molecules in charged droplets (ionization efficiency) and the effective transfer of the charged species from the atmospheric pressure ion source to the high-vacuum MS analyzer (ion transmission efficiency). One of the main efforts in ESI–MS interface technology development is focused on improving both the ionization efficiency in ESI and the ion transmission efficiency through the ESI–MS interface where the majority (> 90%) of the ion loss occurs.

Fundamentals of Electrospray Ionization

It is well recognized that the ESI process consists of four major steps, as illustrated in **Figure 2**, in producing gas-phase analyte ions from liquid solvent: (1) the generation of highly charged droplets, (2) droplet evaporation, (3) droplet fission, and (4) the formation of gas-phase ions. In the first step of the ESI process, highly charged droplets are generated from the electrospray. Their initial size and charge density are mainly determined by the flow rate and liquid properties (e.g., electric conductivity and surface tension). The uniformity of the charged droplets in the electrospray is determined by the electrospray operating regime. Charged droplet evaporation follows droplet generation, during which solvent continuously evaporates from the droplet surface whereas all

Figure 1 Schematic of a standard ESI–MS interface.

Figure 2 Illustration of the major steps in the electrospray ionization process.

the charges are retained in the droplet. This process continues until the droplet size reduces to a critical value at which the total charges on the droplet surface reach a charge limit derived by Rayleigh in 1882 as

$$q_r = (8\pi^2 \epsilon_0 \gamma d^3)^{\frac{1}{2}} \quad [1]$$

where q_r is the charge on the droplet at the Rayleigh limit, γ the liquid surface tension, d the droplet diameter, and ϵ_0 the vacuum electrical permittivity. At the Rayleigh charge limit, the Coulombic repulsion among charges on the droplet surface overcomes the surface tension of the liquid and the droplet disintegrates through a fission process. Droplet fission in electrospray is asymmetric, as captured photographically by Gomez and Tang in 1994 and shown as the inset in **Figure 2**, during which small progeny droplets are ejected from the parent droplet. Numerous experiments also confirm that the parent droplet loses approximately 2% of its mass and 20% of its charge to the progeny droplets in each fission process, implying that gas-phase ions are most likely produced from these highly charged progeny droplets. The droplet evaporation and fission steps may repeat many times in the ESI process depending on the initial droplet size until analyte ions are produced from the charged droplet.

There are two competing mechanisms describing the formation of gas-phase ions from charged droplets. The first mechanism, proposed by Dole in 1968, assumes that the progeny droplets produced by the last fission process are sufficiently small so that some of these droplets contain only a single analyte molecule together with a given number of excess charges. Further solvent evaporation would completely dry the droplet, leaving the 'residue' analyte molecule ionized by the excess charges. This assumption is known as the charged residue model (CRM). The second mechanism, proposed by Iribarne and Thomson in 1976, assumes that the electric field at the surface of the progeny droplets produced by the last fission process reaches a critical value at which ionic analytes start to 'evaporate' from the droplet surface. This mechanism is known as the ion evaporation model (IEM). Although the exact mechanism of how gas-phase ions are produced from the charged droplet is still a heavily

debated subject due to the lack of direct experimental observation, the general consensus is that CRM is the mechanism of choice for large molecules and IEM correctly describes the ionization mechanism for small ionic species.

The key to improving analyte ionization efficiency is to produce smaller droplets with a higher charge density so that fewer droplet evaporation–fission steps are required. The scaling law of electrospray, formulated by Fernandez de la Mora and Locortales in 1994, indicates that droplet size decreases and charge density increases as the liquid flow rate to the electrospray decreases. A high-efficiency ESI source has been developed in which the electrospray operates at tens of nanoliters per minute flow rate. The so-called nanoelectrospray, as proposed by Wilm and Mann in 1996, also allows the ESI emitter to be placed closer to MS inlet, improving the ion transmission efficiency. The ionization efficiency of a given analyte ion depends also on ionic contaminants (matrix effects) or multiple analytes (ion suppression) in the charged droplets. Operating electrosprays in the nanoelectrospray reduces both matrix effect and ion suppression in the ESI process.

Electrospray Operating Regimes

Understanding the behavior of liquids in the absence of an electric field can aid the understanding of the phenomena encountered in its presence. In the case of liquid being continuously supplied at a small rate through a capillary, the liquid drop grows until its weight overcomes the interfacial tension holding it at the tip, and then it pinches off. The liquid recoil following the pinch-off induces a damped oscillation of the meniscus with the characteristic frequency $f_c = (8\gamma/3\pi\rho V)^{1/2}$, where γ , ρ , and V stand for liquid surface tension, density, and volume, respectively. At higher flow rate, the dripping frequency increases because the drops reach their critical weight, W_c , faster. When the dripping frequency approaches f_c , the inertial forces due to liquid oscillation can aid the pinch-off of droplets smaller than W_c , leading to chaotic dripping.

In the presence of an electric field, the electrical forces also promote the pinch-off of droplets smaller than W_c . As long as the weight of the droplets is significant compared to the electrical forces, the electrospray is considered to operate in the 'dripping regime'. Dynamics similar to that of a dripping faucet results when the flow rate is increased while maintaining a constant, relatively small applied voltage. Operation at constant flow rate and increasing voltages assists the generation of smaller droplets at higher dripping frequencies.

Figure 3 presents a sequence of regimes that may be experienced by an electrospray under increasing voltage. As in the case of nonelectrified liquids, the meniscus oscillation due to the recoil following the pinch-off can interfere with the dripping frequency and the droplet size. This is evident during the 'burst regime', characterized by long intervals of inactivity interrupted by trains of liquid ejection events stimulated by the inertial forces during meniscus oscillation. The gap between bursts shortens with increasing voltage.

When the voltage is large enough to sustain liquid ejection during each meniscus oscillation, the electrospray operates in the 'pulsating regime'. The representations in **Figure 3** for burst and pulsation regimes are extremely simplistic and show the result of each liquid ejection event as a single droplet. In reality, the fluid dynamics is considerably more complex in both the burst and pulsating regimes. Each droplet ejection event may be preceded by a plume of smaller droplets with higher charge density, as illustrated further by the inset A in **Figure 3**. A dotted line is superimposed over the continuous line to suggest that each cycle starts with the meniscus deforming into a cone. A liquid jet is ejected through the cone apex and breaks into many smaller droplets. If the charge is supplied electrochemically at a smaller rate than it is ejected through the cone apex, the cone-jet geometry collapses, resulting in the ejection of larger liquid droplets with smaller charge density. The

cycle repeats at a frequency ranging from several kilohertz to more than 100 kHz, depending on the liquid physical properties and the emitter diameter. The process is also too fast for the naked eye or a slow camera to observe the meniscus dynamics; however, the pulsating regime can be identified based on the hallmark overlap between a cone with a blurred apex and a rounded meniscus.

The 'cone-jet regime', as depicted by the inset B in **Figure 3**, generates droplets with very narrow charge and droplet size distributions, characteristics that prompted thorough theoretical and experimental scrutiny. A general theoretical description is not yet available despite the apparent simplicity offered by its steady dynamics. In 1964 Taylor proved that equipotential conical structures with no fluid ejection through the apex could be stable at a semivertical angle of 49.3° . The most popular cone-jet model explains the stability of this geometry by a different charge transport mechanism along the cone surface (conductive) and the jet surface (convective).

The transition from the pulsating to the cone-jet regime with increasing voltage can be sudden or can follow a chaotic, 'astable regime'. During this regime, the electrospray is stable for a limited time in the cone-jet mode characterized by increasing cone volume. When the cone growth becomes unsustainable, the electrospray collapses to a pulsating mode that removes the excess liquid, creating conditions for another switch to the cone-jet mode. The cycle repeats on a timescale that affords observation by the naked eye. Although the regime was systematically described only recently, the fast liquid removal following the cone growth has been observed and is often referred to as spitting.

The current generated by the electrospray is a highly nonlinear function of the applied voltage, which includes two plateaus corresponding to the pulsating and cone-jet regimes. Fast current measurements may capture each liquid ejection event, individual current spikes, trains of

Figure 3 Schematic of different electrospray operating regimes.

pulses, and sinusoidal traces indicating the dripping, burst, and pulsating regimes, respectively. The cone-jet electrospray generates a steady current with approximately twice the magnitude of the pulsating electrospray current. The current trace expected for astable electrosprays is a combination of the traces characteristic to pulsating and cone-jet electrosprays.

When used as an ionization source for MS, the electrospray is expected to provide small droplets that can quickly liberate ions into the gas phase, as well as supply enough charge to effectively ionize the analyte. As a consequence, the large droplets generated by dripping electrosprays are not useful in MS applications. It is generally accepted that the cone-jet electrospray ensures efficient and uniform analyte ionization due to steady production of a high-quality aerosol. However, in conditions characteristic to nanoelectrospray operation, even the pulsating electrosprays may disperse the liquid very efficiently. The bottleneck of ion transmission from atmospheric pressure into the first vacuum stage of the mass spectrometer could actually favor the operation in the pulsating regimen rather than in the cone-jet regime. Electrospray regimes can change during gradient elution LC analyses as a result of changing eluent composition, which in turn can affect performance. Automatic adjustment of the spray voltage using feedback from spray imaging or current measurements can be used to stabilize the electrospray operation in the desired regime.

Electrospray Ionization Source Configurations

More than any other parameter, the appropriate electrospray source for a given analysis is dictated by the liquid flow rate. When used in conjunction with conventional LC separations operated at hundreds of microliters per minute, the large droplets formed by a stand-alone electrospray are insufficiently desolvated, resulting in poor analytic sensitivity. To address this, a sheath gas is generally employed to pneumatically assist the electrospray operation for high-flow analyses. The heated gas jet surrounding the electrospray has a linear velocity $>100\text{ m s}^{-1}$ that quickly nebulizes the liquid stream to create charged droplets having a broad size distribution. The droplets are then able to liberate gas-phase ions through the ESI process. Alternatively, ultrasonic vibration of the emitter has been used as a mechanical means to improve nebulization of high-flow electrosprays.

Despite these advances, sensitivity is still quite poor at high flow rates. As the flow rate is reduced, the size of the primary droplets decreases, reducing the number of Rayleigh fission events needed to generate gas-phase ions. Also, with the reduced requirements for desolvation,

a sheath gas becomes unnecessary and the emitter can be positioned much closer to the MS inlet (e.g., 1–3 mm) for improved ion transmission efficiency. Combined, these advantages lead to a significant sensitivity enhancement at lower flow rates, particularly in the ‘nano-ESI’ regime where zeptomole detection limits have been achieved. Strictly speaking, this regime encompasses flows below 1000 nl min^{-1} , but the benefit of nano-ESI becomes more noticeable below 100 nl min^{-1} . To achieve a stable spray at low nanoliters per minute flow rates, emitter geometry becomes critical. Traditional stainless steel emitters cannot be machined to sufficiently small dimensions to stabilize an electrospray at these low flows, which has led to the widespread use of emitters made from fused silica capillaries. These emitters were originally fabricated by heating and pulling the capillary to draw the tubing to a narrow orifice with a diameter of a few micrometers. A well-drawn emitter can achieve stable sprays at low flows, but several disadvantages of the approach persist. For example, reproducibility between emitters is generally poor if made by hand, and because the inner diameter of the capillary tapers to a narrow orifice, any debris or particulate matter can easily clog the emitter, leading to short emitter lifetimes. Chemically etched fused silica emitters, developed by Kelly et al. in 2006, overcome these challenges. The emitters are created by inserting the bare end of a fused silica capillary in hydrofluoric acid (HF) solution while pumping a small amount of water through the tube to prevent etching of the interior. When the capillary in contact with the HF is completely etched away, an externally tapered emitter with extremely thin orifice walls is obtained. A photograph of a chemically etched emitter is shown in **Figure 4**. The lack of mechanical processing or internal taper enables robust, stable operation of electrospray at lower flows for a given inner diameter relative to pulled emitters. As an example, a $20\text{-}\mu\text{m}$ -i.d. etched emitter can operate routinely at $10\text{--}20\text{ nl min}^{-1}$ and can also be used at flow rates as high as several microliters per minute.

Besides stainless steel and capillary-based emitters, significant progress has been made in the development of microfabricated emitters. The most prominent of these is the commercially available ESI ChipTM by Advion (Ithaca, NY), which comprises an array of hundreds of individual nano-ESI emitters that are microfabricated in silicon and used individually for single analyses. In addition, numerous approaches have been developed to couple microfluidic (lab-on-a-chip) devices with MS detection using integrated electrospray emitters. A review by Koster and Verpoorte in 2007 offers extensive information on this topic.

The approach used to provide electrical contact for the electrospray depends on the emitter material as well as on the application. High voltage can be applied directly to stainless steel emitters, whereas for fused silica

Figure 4 A-20- μm i.d. chemically etched nanoelectrospray emitter.

capillaries, contact can be conveniently applied upstream through a zero-dead-volume metal union connecting the emitter to an LC column. For self-fed nano-ESI, in which the electrospray process itself provides the only mechanism for sample delivery, as well as for sheathless coupling with capillary electrophoresis separations, electrical contact must be provided at the emitter orifice. Various methods have thus been developed to metalize or otherwise render conductive the fused silica capillary surface.

Although operation of the electrospray at low nanoliters per minute flow rates enables the greatest MS sensitivity, performing an analysis at these flows is not always practical. For example, for LC-ESI-MS, a number of commercially available systems now operate robustly at hundreds of nanoliters per minute to improve electrospray performance, but further decreasing the flow to take full advantage of the improved sensitivity afforded by nano-ESI has proven challenging for routine use. To extend the benefits of nano-ESI to higher flow rate analyses, arrays of electrospray emitters have been developed. This approach enables the benefits of higher flow capillary LC separations (improved robustness and greater sample loading capacity) and low-flow electrospray (increased sensitivity) to be achieved simultaneously. Both microfabricated and capillary-based multi-nanoelectrospray emitters have been developed. A photograph of a capillary-based emitter array comprising 20 individual emitters each operating at 50 nl min^{-1} is illustrated in **Figure 5**.

Electrospray Ionization–Mass Spectrometry Interface

The relative ease in creating gas-phase ions, ranging in size from elemental cations to large proteins covering well over a megadalton, has propelled the use and development of ESI in instrumentation. However, to perform analytical measurements of these ions, the ESI source must be interfaced with the instrument of choice. Some instrumentation lends itself to a relatively easy coupling such as atmospheric pressure ion mobility

Figure 5 Capillary-based multi-nanoelectrospray source composed of 20 emitters interfaced with a multicapillary MS inlet. The total flow rate is $1\text{ }\mu\text{l min}^{-1}$.

spectrometry where a gas-phase separation occurs at the same pressure as the ESI source, whereas other instrumentation, such as MS, requires more complex technologies to both desolvate and effectively transmit ions through several stages of decreasing pressure to the lower pressure region of the mass analyzer. This has produced a variety of approaches in creating efficient interfaces to couple ESI to the MS analyzer to effectively desolvate/decluster the analyte ions and transmit them with high efficiency.

In the early examples of using ESI for MS by Fenn et al., a high voltage applied to a hypodermic needle electrosprayed sample solution into a counter-flowing heated nitrogen gas. A small orifice located a short distance downstream of the needle sampled a portion of the ions into the mass spectrometer via a skimmer and radio frequency (RF) ion guide. This design was further refined and is currently used on many commercial ESI-MS instruments, such as MDS Sciex models, and is commonly referred to as a curtain gas/orifice interface (**Figure 6(a)**). A heated curtain gas serves to desolvate

Figure 6 Schematic of different ESI-MS interfaces: (a) curtain gas/orifice-skimmer interface, (b) heated capillary-skimmer interface, (c) multicapillary-ion funnel interface, and (d) SPIN source interface.

the solvent from the electrospray droplets and also to decluster, or remove the final solvent molecules from, the analyte ions. In addition, the counter-flowing gas reduces the amount of solvent entering the vacuum region of the interface where the rapid jet expansion can cause recluster of the solvent to the analyte. The skimmer is positioned in the vacuum region behind the orifice in the expanding gas jet, which is well characterized by a barrel-shaped shock wave and a Mach disk separating the supersonic jet from the subsonic gas flow. The skimmer can be placed before the Mach disk in the 'zone of silence' where the gas density is lower and ions are more effectively focused through the skimmer, or after the Mach disk, which can lower the ion transmission efficiency but also reduce the gas load to the following MS vacuum chamber and the pumping requirements for the instrument. An accelerating potential can also be applied between the orifice plate and the skimmer to provide

further declustering through collisions between ion clusters and the background gas. An alternative to the orifice inlet is the use of a long heated capillary, having a typical i.d. of 0.5–0.7 mm and a length of 6–10 cm. Desolvation and declustering occurs as the droplets are transmitted through the heated inlet, which can remove the requirement of a curtain gas (**Figure 6(b)**). The heated capillary-skimmer interface is also found on many commercial mass spectrometers (e.g., Thermo Fisher and Agilent Technologies models) using either metal or glass capillaries.

Desolvation and declustering is the primary function of both the orifice and capillary-skimmer interfaces, whereas transmission efficiency is typically optimized by changing the conductance of the orifice or capillary. Although the small size of the skimmer aperture (~ 1 mm in diameter) is needed to maintain the required vacuum in the MS analyzer, it significantly limits the ion

transmission efficiency. To greatly reduce this major interface ion loss, an electrodynamic ion funnel interface was developed by Smith et al. at Pacific Northwest National Laboratory as a replacement to the skimmer (**Figure 6(c)**). In contrast to the skimmer interface, the ion funnel can focus ions in a broad range of m/z ratio exiting the inlet capillary and transmit them through a conductance limiting orifice with approximately 100% efficiency at no increase in pumping requirement. A typical ion funnel design consists of a series of ring electrodes with a front section of constant i.d., creating a traditional stacked ring ion guide, and a back section that linearly decreases in i.d., creating an 'ion funnel'. A superimposed RF voltage and DC gradient is applied to the rings, which confines and transmits the ions through the device. A recent study showed that an approximately 10-fold increase in ion beam intensity can be gained by simply replacing the skimmer with an ion funnel in linear ion trap mass spectrometers. Another advantage of the ion funnel is its large ion capture region determined by the i.d. of the initial funnel electrodes. This allows for unique inlet configurations to further increase the MS sensitivity. Since the ion sampling efficiency of an orifice or capillary inlet is limited by its open area where ions are dragged into the inlet by the gas flow, a multicapillary/orifice inlet coupled with ion funnel was developed to increase both ion sampling and transmission efficiencies (**Figure 6(c)**). To further increase the ion production rate, a multi-electrospray ion source can be integrated with the multicapillary/orifice-ion funnel interface, as illustrated partially in **Figure 5**.

Although a multicapillary-ion funnel interface significantly increases the MS sensitivity, the inherent large ion loss in the capillary still limits the transmission efficiency through the ESI-MS interface. A potential breakthrough technology is to move the ESI source inside the first MS vacuum chamber and operate the electrospray at a reduced pressure to completely eliminate the need for a capillary/orifice inlet in the ESI-MS interface. The low-pressure ESI interface developed by Page et al. in 2008, known as subambient pressure ionization with nanoelectrospray (SPIN) and shown in **Figure 6(d)**, uses small (5–10 μm i.d.), chemically etched emitters positioned directly at the inlet of an ion funnel, where both the ESI source operation and the ion transmission occur at a pressure of approximately 30 Torr. The pressure in the SPIN source-ion funnel interface is low enough for the ion funnel to effectively confine and transmit ions and high enough to provide adequate desolvation and declustering without electrical discharge in the ESI source operation. Using the SPIN source for the LC-MS analysis of a protein digest showed a 5- to 10-fold increase in intensity for a range of tryptic peptides compared to using a heated capillary (480 μm i.d.,

7.6 cm long)—ion funnel interface. Since all the analyte eluting from the LC column is electrosprayed into the ion funnel, additional sensitivity increase is expected as desolvation and declustering at the lower pressure is further improved.

Symbols

A	Bessel angle of PEM modulation, amplitude
d	film thickness
I_T	total intensity element of Stokes vector
I_n	element of Stokes vector, intensity of light linearly polarized at n degrees
J_n	Bessel functions
J	Jones matrix
k	extinction coefficient
M	Mueller matrix, normalized
$M_{M,J}$	Mueller–Jones matrix
n	refractive index
N_0, N_t, N_s	complex refractive indices
r_p, r_s, etc.	complex reflection coefficients
S	Stokes vector
V	voltage, $I_{rc} - I_{lc}$ element of Stokes vector
α	absorption coefficient
δ_c	constant phase shift
Δ	ellipsometry angle
θ	azimuthal angle
λ	wavelength
ρ	complex reflection ratio
ϕ	angle of incidence
ϕ_t, ϕ_s	complex angles
χ^2	figure of merit
ψ	ellipsometry angle
ω	angular frequency

Ellipsometry is a technique often used to measure the thickness of a thin film. Generally speaking, the measurement is performed by polarizing the incident light beam, reflecting it off a smooth sample surface at a large oblique angle and then re-polarizing the light beam before the intensity of the light beam is measured. Since the process of reflecting light off a smooth sample surface generally changes linearly polarized light into elliptically polarized light, the technique has been called ‘ellipsometry’.

The earliest ellipsometry measurements (ca 1890) were used to determine the optical functions (refractive

index n and extinction coefficient k , or equivalently, absorption coefficient α) for several materials. In the 1940s it was discovered that a single-wavelength nulling ellipsometry measurement could be used to determine the thickness of certain thin films very accurately. Since that time, single-wavelength ellipsometry has evolved to be the standard of thickness measurement for several industries, including the semiconductor industry.

Ellipsometry experiments produce values that are not useful by themselves: computers must be used to obtain useful quantities such as thin-film thickness or the optical functions of materials. The advent of modern computers resulted in the invention of several spectroscopic ellipsometers and the creation of more realistic analysis programs required to understand spectroscopic ellipsometry data.

Any ellipsometer (see **Figure 1**) consists of five elements: (1) a light source, (2) a polarization state generator (PSG), (3) a sample, (4) a polarization state detector (PSD), and (5) a light detector. The light source can be a monochromatic source, such as from a laser, or a white light source, such as from a xenon or mercury arc lamp. The PSG and PSD are optical instruments that change the polarization state of a light beam passing through them and they contain optical elements such as polarizers, retarders and photoelastic modulators. In most ellipsometry experiments, light from the PSG is reflected from the sample surface at a large angle of incidence ϕ . Spectroscopic ellipsometers use a white light source and a monochromator (either before the PSG or after the PSD) to select out specific wavelengths. Some

Figure 1 Schematic diagram of an ellipsometer. The PSG is the polarization state generator and the PSD is the polarization state detector.

spectroscopic ellipsometers image the white light from the PSD onto a detector array, thereby allowing the whole spectrum to be collected simultaneously.

Any ellipsometer will only measure characteristics of the light reflected from or light transmitted through the sample. Ellipsometers do not measure film thicknesses or optical functions of materials, although these parameters can often be inferred very accurately from the ellipsometry measurements. Data analysis is an essential part of any ellipsometry experiment.

Polarization Optics

Several optical elements will change the polarization state of a light beam interacting with them. Linear polarizers (see **Figure 2a**) transmit only one polarization of the light beam; the azimuthal angle of the polarizer will determine the azimuthal angle of the light polarization. The best linear polarizers in the visible part of the spectrum are prism polarizers made from birefringent crystals such as calcite, magnesium fluoride or quartz, which have refractive indices that depend upon the direction in the material.

Figure 2 Several optical elements used in ellipsometers that alter the polarization state of a light beam passing through them. (a) A linear polarizer, which transforms any light beam (polarized or unpolarized) to linearly polarized light. (b) A retarder, which transforms linearly polarized light to elliptically polarized light. In certain cases, the light can be circularly polarized. (c) A photoelastic modulator, which changes linearly polarized light into dynamically elliptically polarized light.

Retarders or compensators (see **Figure 2b**) are another common type of optical element used in ellipsometers. In combination with a polarizer, a retarder can produce circularly or elliptically polarized light if the direction of the linear polarization is not parallel to a major axis in the retarder. Static retarders, such as quarter-wave or half-wave plates, produce a fixed amount of retardation at a fixed wavelength. Circularly polarized light can be produced from a polarizer–quarter-wave retarder pair if the light polarization is $\pm 45^\circ$ with respect to the fast axis of a retarder.

Another common retarding element used in spectroscopic ellipsometers is the photoelastic modulator (PEM), shown schematically in **Figure 2c**. The drive element is a crystal quartz bar, which is cut so that an a.c. voltage V applied to the front and back faces causes the bar to vibrate along its long axis at the frequency of V . The optical element is a bar made of fused quartz that is placed in intimate contact with the crystal quartz bar so that it vibrates at the same frequency. Both bars are sized so that the vibrations are resonant, making the frequency of the PEM extremely stable. A polarizer–PEM pair produces dynamically elliptically polarized light if the polarizer is not lined up with the vibration axis of the PEM; generally, the polarization state of the emergent light beam will cycle through linearly polarized, circularly polarized and elliptically polarized states.

The Stokes vector representation of light polarization has often been used for ellipsometry measurements. (Another representation is the Jones vector representation, of which details can be found in the book by Azzam and Bashara listed under Further Reading.) In the Stokes representation, the polarization state of a light beam is given by its four-element Stokes vector,

$$S = \begin{bmatrix} I_0 \\ Q \\ U \\ V \end{bmatrix} = \begin{bmatrix} I_0 \\ I_0 - I_{90} \\ I_{45} - I_{-45} \\ I_{rc} - I_{lc} \end{bmatrix} \quad [1]$$

All the elements of the Stokes vector are intensities and therefore are real. The total intensity is I_T , while I_0 , I_{90} , I_{45} , and I_{-45} are the intensities of linearly polarized light at 0° , 90° , 45° , and -45° , respectively. The fourth element of the Stokes vector V is the difference between the intensities of right circularly polarized light I_{rc} and left circularly polarized light I_{lc} . A linear polarizer can only transform a light beam into a linear polarization state; therefore the fourth element of the Stokes vector for linearly polarized light will be $V = 0$. Generally, a retarding optical element is needed to transform the polarization state of a light beam to one where $V \neq 0$. The Stokes representation can also represent partially

polarized light. In general,

$$I_T \geq \sqrt{Q^2 + U^2 + V^2} \quad [2]$$

where the equality holds when the light beam is totally polarized.

Each optical element must transform the polarization state from one four-element vector to another four-element vector; therefore, optical elements are represented by 4×4 Mueller matrices, where all the elements are real. The intensity of the light beam passing through an ellipsometer can therefore be written using matrix notation as

$$I = \mathbf{S}_{\text{PSD}}^T \mathbf{M} \mathbf{S}_{\text{PSG}} \quad [3]$$

where $\mathbf{S}_{\text{PSG}}$ is the Stokes vector representing the polarization state for light coming from the PSG, $\mathbf{M}$ is the Mueller matrix for the light interaction with the sample, and $\mathbf{S}_{\text{PSD}}^T$ is the transpose of the Stokes vector representing the effect of the PSD. In the most general case, 16 elements are required to describe the light interaction with a sample. Fortunately, many of these elements are normally 0 or equal to another element in $\mathbf{M}$. Since detectors can only measure the light intensity coming from an instrument, eqn [3] emphasizes the fact that ellipsometers can only measure elements of $\mathbf{M}$.

Ellipsometry Data Analysis

Ellipsometry measurements are not useful by themselves but can be extremely useful if the measurements are interpreted with an appropriate model. Ultimately, ellipsometry results are always model dependent. Fortunately, the physics of light reflection from surfaces is well understood, and very detailed and accurate models can be made using classical electromagnetic theory based on the Maxwell equations.

Figure 3 shows a schematic of light reflection from a sample surface. The light beam is incident upon the sample surface at an angle of incidence ϕ . The specularly reflected beam comes from the sample surface, also at angle ϕ . The incident and reflected beams define a plane, called the plane of incidence. This in turn defines two polarization directions: p for the light polarization parallel to the plane of incidence (in the plane of the paper), and s for the light polarization perpendicular to the plane of incidence (perpendicular to the plane of the paper). All azimuthal angles are defined with respect to the plane of incidence, where positive rotations are defined as clockwise rotations looking from the light source to the detector.

If the sample surface is isotropic and has no film or other overlayer ($d = 0$ in **Figure 3**), then one can use the Maxwell equations to calculate the complex reflection

Figure 3 A schematic diagram of light reflecting from a sample surface. The s and p vectors indicate the direction of s and p polarized light, as defined by the plane of incidence. The angle of incidence is ϕ , and N_0 , N_f and N_s are the complex refractive indices of the ambient, film and substrate, respectively.

coefficients:

$$r_p = \frac{N_s \cos(\phi_0) - N_0 \cos(\phi_s)}{N_s \cos(\phi_0) + N_0 \cos(\phi_s)} \quad [4a]$$

$$r_s = \frac{N_0 \cos(\phi_0) - N_s \cos(\phi_s)}{N_0 \cos(\phi_0) + N_s \cos(\phi_s)} \quad [4b]$$

In eqns [4], N_0 and N_s ($= n_s + ik_s$, where n_s is the refractive index and k_s is the extinction coefficient) are the complex indices of refraction for the ambient (usually air, where $N_0=1$) and the substrate, respectively. The quantities ϕ_0 and ϕ_s are complex angles, determined from the Snell law [$N_0 \sin(\phi_0) = N_s \sin(\phi_s)$]. The reflection ratios r_p and r_s are complex, indicating that light reflected from a surface will generally undergo a phase shift.

If the sample near-surface region consists of a single film (see **Figure 3**), the composite reflection coefficients can be calculated from the Airy formula:

$$r_{s,p} = \frac{r_{1s,p} + r_{2s,p} e^{-2ib}}{1 + r_{1s,p} r_{2s,p} e^{-2ib}} \quad b = \frac{2\pi d N_f(\phi_f)}{\lambda} \quad [5]$$

where d is the thickness of the film, N_f is the complex refractive index of the film, and ϕ_f is the complex angle within the film defined by the Snell law. The quantities $r_{1s,p}$ and $r_{2s,p}$ are the complex reflection coefficients calculated using eqns [4a] and [4b] for the air–film interface and the film–substrate interface, respectively.

Reflections from more complicated layer structures can be calculated using matrix methods. If all the media in the calculation are isotropic, the matrix formulation of Abelés (using 2×2 complex matrices) can be used to calculate the composite r_s and r_p .

If any of the media are birefringent, many of the implicit assumptions made above are no longer valid. For example, for isotropic media the s and p polarization

states represent eigenmodes of the reflection; that is, if the incoming light is pure s or p polarized, then the reflected light will be pure s or p polarized. If any of the media in the sample are birefringent, this assumption is no longer generally valid. As a result, one must also calculate the cross-polarization coefficients r_{sp} and r_{ps} as well as $r_{ss} \equiv r_s$ and $r_{pp} \equiv r_p$. If $r_{sp} \neq 0$ or $r_{ps} \neq 0$, the 2×2 matrix methods must be replaced by more complicated 4×4 matrix methods.

Up to this point, a clear distinction has been drawn between the parameters measured by an ellipsometer (the sample Mueller matrix $\mathbf{M}$) and the calculated parameters obtained from classical electromagnetic theory, which can be expressed as elements of the sample Jones matrix:

$$\mathbf{J} = \begin{bmatrix} r_{pp} & r_{ps} \\ r_{sp} & r_{ss} \end{bmatrix} \quad [6]$$

Fortunately, the two representations are related, so long as it can be assumed that the sample does not depolarize the incident light beam. In this case, a Mueller–Jones matrix $\mathbf{M}_{MJ}$ can be calculated from the elements of the Jones matrix (eqn [6]),

$$\mathbf{M}_{MJ} = \mathbf{A}(\mathbf{J} \otimes \mathbf{J}^*)\mathbf{A}^{-1} \quad [7a]$$

where

$$\mathbf{A} = \begin{bmatrix} 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & -1 \\ 0 & 1 & 1 & 0 \\ 0 & -i & i & 0 \end{bmatrix} \quad [7b]$$

For isotropic samples ($r_{sp} = r_{ps} = 0$), the normalized sample Mueller–Jones matrix is given by

$$\mathbf{M} = \mathbf{M}_{MJ} = \begin{bmatrix} 1 & -N & 0 & 0 \\ -N & 1 & 0 & 0 \\ 0 & 0 & C & S \\ 0 & 0 & -S & C \end{bmatrix} \quad [8a]$$

where

$$N = \cos(2\psi) \quad [8b]$$

$$S = \sin(2\psi)\sin(\Delta) \quad [8c]$$

$$C = \sin(2\psi)\cos(\Delta) \quad [8d]$$

$$\rho = \frac{r_p}{r_s} = \tan(\psi)e^{i\Delta} = \frac{C + iS}{1 + N} = \rho_r + i\rho_i \quad [8e]$$

The angles ψ and Δ are the traditional ellipsometry angles, and are the naturally measured parameters for nulling ellipsometers (see below). The matrix $\mathbf{M}$ simplifies considerably when the sample is isotropic: $\mathbf{M}$ is block-diagonal, with eight elements equal to 0, and only two parameters (such as $\rho = \rho_r + i\rho_i$ or ψ and Δ) are needed to specify $\mathbf{M}$, since $N^2 + S^2 + C^2 = 1$.

For birefringent samples, $r_{sp} \neq r_{ps} \neq 0$, and the off-block diagonal elements of $\mathbf{M}$ are no longer 0, nor are the on-block diagonal elements of $\mathbf{M}$ so simply defined. However, eqn [7a] is still valid as long as the sample is nondepolarizing. In this case, six parameters are required to specify all 16 elements of the normalized sample Mueller matrix, given by eqn [8e] and

$$\rho_{ps} = \frac{r_{ps}}{r_{ss}} = \tan(\psi_{ps})e^{i\Delta_{ps}} = \frac{C_{ps} + iS_{ps}}{1 + N} \quad [8f]$$

$$\rho_{sp} = \frac{r_{sp}}{r_{ss}} = \tan(\psi_{sp})e^{i\Delta_{sp}} = \frac{C_{sp} + iS_{sp}}{1 + N} \quad [8g]$$

Up to now, we have assumed that no optical element depolarizes the light. Usually, this is true, but there are some cases where depolarization must be considered. (1) If the input light beam illuminates an area of the sample where the film thickness(es) is (are) not uniform, quasi-depolarization can occur. (2) If the sample substrate is transparent, then light reflecting from the back surface will contribute an intensity component to the light beam entering the PSD that is not phase-related to the light reflected from the front face and the light beam will be quasi-depolarized. (3) If the sample is very rough, then some of the light reaching the PSD will not have an identifiable polarization state or cross-polarization can occur in nominally isotropic systems. All of these effects invalidate the Mueller–Jones matrix representation of the sample surface shown in eqn [7a].

Types of Ellipsometers

There are many different kinds of ellipsometers, some of which are shown schematically in **Figure 4**. All ellipsometers measure one or more quantities that can be related to the complex reflection coefficient ratio ρ shown in eqns [8].

Nulling Ellipsometer

The oldest and most common type of ellipsometer is the nulling ellipsometer, shown schematically in **Figure 4a**. The light source for a modern nulling ellipsometer is usually a small laser, but other monochromatic sources can also be used. The PSG is a polarizer–retarder pair,

Figure 4 Schematic diagrams of three ellipsometers in common use. (a) The nulling ellipsometer, which normally uses monochromatic light. (b) The rotating analyser ellipsometer. (c) The polarization modulation ellipsometer.

and the PSD is a linear polarizer, historically called the analyser. If the quarter-wave plate is oriented at 45° with respect to the plane of incidence, the intensity of the light beam incident upon the detector is given by

$$I = I_0[1 - N\cos(2\theta_a) + \sin(2\theta_a)(C\sin(2\theta_p) + S\cos(2\theta_p))] \quad [9]$$

where θ_p and θ_a are the azimuthal angles of the polarizer and analyser, respectively, and N , S and C are the quantities given in eqns [8]. The intensity given in eqn [9] has a null at two sets of angles: $(2\theta_p, \theta_a) = (270^\circ - \Delta, \psi)$, $(90^\circ - \Delta, 180^\circ - \psi)$. Therefore, nulling ellipsometry measurements are made by rotating the PSG polarizer and the PSD polarizer (analyser) until the light intensity reaching the detector is a minimum. The angles ψ and Δ are determined from the azimuthal angles of the PSG and PSD polarizers.

The nulling ellipsometer is one of the simplest ellipsometers and it is capable of very accurate measurements with proper calibration. However, it normally uses a single-wavelength source and it is not easily made spectroscopic. Moreover, measurement times are slow, so

this type of instrument is not useful for spectroscopic ellipsometry or for fast time-resolved measurements.

Rotating Analyser Ellipsometer (RAE)

The most common type of spectroscopic ellipsometer is the rotating analyser (or rotating polarizer) ellipsometer, shown schematically in **Figure 4b**. The PSG is a linear polarizer, as is the PSD, and one of the optical elements (the analyser in **Figure 4b**) is physically rotated, making the light intensity at the detector a periodic function of time. For an analyser (PSD) rotating at an angular frequency of ω and with the polarizer (PSG) set at an azimuthal angle of θ_p , the intensity is given by

$$I(t) = I_0[1 + \alpha \cos(2\omega t + \delta_c) + \beta \sin(2\omega t + \delta_c)] \quad [10a]$$

where

$$\alpha = \frac{\cos(2\theta_p) - N}{1 - N\cos(2\theta_p)} \quad [10b]$$

$$\beta = \frac{C\sin(2\theta_p)}{1 - N\cos(2\theta_p)} \quad [10c]$$

The quantity δ_c is a constant phase shift. The coefficients α and β can be determined using demodulation techniques or Fourier analysis. Normally, $\theta_p = 45^\circ$, where $\alpha = -N$, and $\beta = C$.

In its normal form, the RAE includes only polarizers, although a retarder can be added to either the PSG or the PSD. If only polarizers are used, this instrument is very easy to make spectroscopic, since no optical component other than the sample is wavelength dependent. Furthermore, the measurement time depends principally on the rotation speed of the rotating element. For a rotation speed of 100 Hz, measurements can be completed in 40 ms. In some configurations of the rotating polarizer ellipsometer, a spectrograph is placed after the PSD and the light is detected by a photodiode array. This ellipsometer can collect an entire spectrum with a single series of measurements, typically taking about 1 s to collect and analyse each spectrum.

The RAE measures two quantities, N and a linear combination of C and S . If there is no retarder, the RAE measures N and C , and will therefore be subject to large errors in Δ if Δ is near 0° or 180° and an uncertainty of the sign of Δ . The use of a quarter-wave retarder shifts the inaccuracy in Δ to the regions near $\pm 90^\circ$.

Photoelastic Modulator Ellipsometer (PME)

Another common spectroscopic ellipsometer is based on the photoelastic modulator (PEM), shown in **Figure 4c**.

Normally, the PSG consists of a polarizer–PEM pair, where the polarizer is oriented at 45° with respect to the vibration axis of the PEM (see **Figure 2c**). The intensity of the light arriving at the detector is a function of time given by

$$I(t) = I_0[I_{dc} + I_X \sin(A \sin \omega t) + I_Y \cos(A \sin \omega t)] \quad [11a]$$

where

$$I_{dc} = 1 - N \cos(2\theta_a) \quad [11b]$$

$$I_X = S \sin(2\theta_a) \quad [11c]$$

$$I_Y = \sin(2\theta_m)[\cos(2\theta_m) - N] - C \cos(2\theta_m) \sin(2\theta_a) \quad [11d]$$

The quantity A is the Bessel angle of the PEM modulation, and is proportional to the amplitude of modulation; normally, this is set at 2.4048 radians. The frequency of the PEM is denoted by $2\pi\omega$, and is normally ~ 50 kHz. The quantities θ_m and θ_a are the azimuthal angles of the modulator and the PSD polarizer, respectively.

The time dependence of the light intensity from the PME is considerably more complicated than that from the RAE, since the basis functions are $\sin(A \sin(\omega t))$ and $\cos(A \sin(\omega t))$, rather than $\sin(\omega t)$ and $\cos(\omega t)$ as for the RAE. However, these functions can be expressed in terms of a Fourier–Bessel infinite series:

$$\sin(A \sin(\omega t)) = 2 \sum_{k=1}^{\infty} J_{2k-1}(A) \sin((2k-1)\omega t) \quad [12a]$$

$$\cos(A \sin(\omega t)) = J_0(A) + 2 \sum_{k=1}^{\infty} J_{2k}(A) \cos(2k\omega t) \quad [12b]$$

Therefore, a demodulation or Fourier analysis of the waveform of eqn [11a] can also be used to get the coefficients I_X and I_Y .

The PME is more complicated than the RAE, since the modulation amplitude of the PEM must be calibrated and its small but significant static retardation measured at all wavelengths used. Furthermore, the frequency of the PEM is about 500 times faster than the rotation speed of the RAE; this improves the time resolution to ~ 1 ms, but requires faster electronics for data collection. In its normal configuration discussed above, the PME can measure S and either N or C . However, if the PSD polarizer is replaced with a Wollaston prism polarizer and both channels are detected (measuring a total of four quantities), then it is possible to measure N , S , and C simultaneously. This implementation is called the two-channel spectroscopic polarization modulation ellipsometer (2C-SPME).

Other Configurations

The ellipsometer configurations discussed above are particularly useful if the sample is isotropic. If the sample is anisotropic, then many of the simplifications used above are not valid, and many more measurements must usually be made, since the normalized sample Mueller matrix contains six independent quantities. One such implementation is the two-modulator generalized ellipsometer (2-MGE) which uses two PEMs operating at different frequencies. The 2-MGE is spectroscopic and is capable of measuring all six independent elements of the sample Mueller matrix simultaneously. Other configurations are discussed in the review article by Hauge.

Application: Silicon Dioxide Films on Silicon

One of the most useful applications of ellipsometry has been the routine measurement of silicon dioxide (SiO_2) film thicknesses grown on silicon. Since the refractive index of SiO_2 is well known, and does not depend significantly on film deposition technique, nulling ellipsometry measurements are usually sufficient to determine film thickness.

Figure 5 shows a plot of ψ versus Δ for thin-film SiO_2 grown on silicon for a wavelength of 633 nm (the wavelength of a HeNe laser). The angle of incidence used for the calculation was 70° , the film refractive index $n_f = 1.46$, and the complex refractive index of silicon $N_s = n_s + ik_s = 3.86 + i0.018$. This plot shows the trajectory that $\psi - \Delta$ follows as the film thickness increases from zero to

Figure 5 The $\psi - \Delta$ trajectory for a thin film of SiO_2 on silicon. The angle of incidence $\phi = 70^\circ$, $n_f = 1.46$, $N_s = 3.86 + i0.018$, and the wavelength $\lambda = 633$ nm (HeNe laser).

~ 280 nm, where the position along the trajectory for several thicknesses is noted in the figure. For zero film thickness, the value of Δ is very close to 0° or 180° , owing to the very small value of k_s . If other film refractive indices were included in this plot, it would be seen that they would converge to this point. It is therefore very difficult to determine the refractive index and the thickness of a very thin film from ellipsometry measurements. Note that the curve comes around on itself near 283 nm. Therefore, any ellipsometry measurement of SiO_2/Si can only be used to determine the film thickness modulo the repeat thickness (283 nm). For film thicknesses from 140 to 160 nm, the measurements are very sensitive to film thickness, crossing the $\Delta = 180^\circ$ point for a thickness of 141.5 nm (half the repeat thickness).

The same data are plotted in a different manner in **Figure 6**. Here, the complex $\rho (= \tan(\psi) e^{i\Delta})$, see eqn [8e] is plotted versus film thickness. Near zero thickness, $\text{Im}(\rho)$ (which is proportional to $\sin(\Delta)$) is very small. As the thickness approaches 140 nm, $-\text{Re}(\rho)$ gets very large and $\text{Im}(\rho)$ changes sign ($\text{Im}(\rho) = 0$ at half the repeat thickness); this corresponds to the region of large ψ in **Figure 5**, with the change in the sign of $\text{Im}(\rho)$ corresponding to Δ going through 180° . Again, the value of ρ repeats itself after 283 nm.

Figures 7a–c, show the measured values of ρ for three thicknesses of SiO_2 films grown on silicon (66 nm, 190 nm and 321 nm) at an angle of incidence of 65° . There are several points where $\text{Im}(\rho) = 0$ and where $-\text{Re}(\rho)$ is a maximum: ~ 335 nm for the 66 nm film; ~ 305 nm for the 190 nm film; and ~ 315 nm and ~ 505 nm for the 321 nm film. Using spectroscopic ellipsometry for this system is similar to sampling several points along the $\psi - \Delta$

trajectory shown in **Figure 5**, although the precise values of the null points of $\text{Im}(\rho)$ will not scale, since N_f and N_s are both functions of wavelength.

Spectroscopic Ellipsometry Data Analysis

It is easy to see that there are more than 100 data points in each of **Figures 7a–c**, but only a few parameters to be determined from the data; the problem is over-determined. Therefore, fitting procedures must be used to determine film thicknesses and other properties of thin films from spectroscopic ellipsometry. This process has three steps: (1) model the near-surface region of the sample; (2) parametrize or determine the optical functions of each layer; (3) fit the data using a realistic figure of merit to measure the ‘goodness of fit’. For the case of SiO_2 grown on silicon, a four-media model is used, consisting of air/ SiO_2 /interface/silicon. The optical functions of the SiO_2 layer are assumed to follow the Sellmeier approximation:

$$n^2 = 1 + \frac{A\lambda^2}{\lambda^2 - \lambda_0^2} \quad [13]$$

where the two possible fitting parameters are the amplitude A and the resonance wavelength λ_0 . The interface is assumed to be a thin layer whose optical functions are those of a Bruggeman effective medium, consisting of 50% SiO_2 and 50% Si, and the optical functions of silicon are taken from the literature. Using this model, three parameters are determined in the fitting procedure (listed in **Table 1**): the film thickness d_f , A from eqn [12] and the thickness of the interface $d_{\text{interface}}$; the resonant wavelength $\lambda_0 = 92.3$ nm. The third step of the analysis involves the actual fitting of the calculated values of ρ with the measured values of ρ . This can be done using a Levenberg–Marquardt algorithm to solve for the fitted parameters $d_{\text{interface}}$, d_f and A using the reduced χ^2 as the figure of merit:

$$\chi^2 = \frac{1}{N - m - 1} \sum_{i=1}^N \frac{(\rho_{\text{exp}}(\lambda_i) - \rho_{\text{calc}}(\lambda_i, \mathbf{z}))^2}{\delta \rho_{\text{exp}}^2(\lambda_i)} \quad [14]$$

The sum in eqn [14] is taken over N wavelength points (λ_i), $\mathbf{z}$ is a vector of the fitted parameters (in this case, $d_{\text{interface}}$, d_f and A), and m is the dimensionality of $\mathbf{z}$ (i.e. 3). The quantities in the denominator ($\delta \rho_{\text{exp}}^2(\lambda_i)$) are the errors in the experimental data. The χ^2 is a good metric for the ‘goodness of fit’ to ellipsometry data. If χ^2 is near 1, the fit is a good fit, but if it is much greater than 1, the model does not fit the data. After the parameters are determined, it is also necessary to calculate the error limits as well as the correlation coefficients of all the fitted parameters.

Figure 6 The complex reflection ratio ρ for the system described in **Figure 5**.

Figure 7 The spectroscopic values of the complex reflection ratio ρ for three samples of SiO_2 films grown on silicon as measured by spectroscopic ellipsometry. The three different thicknesses are (a) 66 nm, (b) 190 nm and (c) 321 nm.

Table 1 The results of the fitting procedure on the spectroscopic ellipsometry data taken on several thin-film SiO₂/Si samples, shown in **Figures 7a–c**. The refractive index is calculated from eqn [13] assuming $\lambda_0 = 92.3$ nm

Sample	Film thickness (nm)	A	Refractive index (600 nm)	Interface thickness (nm)	χ^2
a	66.4 ± 0.1	1.149 ± 0.002	1.475	0.0 ± 0.2	0.18
b	188.9 ± 0.3	1.115 ± 0.003	1.464	1.4 ± 0.2	1.21
c	321.5 ± 0.4	1.139 ± 0.003	1.472	1.0 ± 0.2	0.84
Fused silica	—	1.099	1.458	—	—

The results of the fits to the data presented in **Figures 7a–c** are shown in **Table 1**, as well as the errors of each of the fitted parameters and the final χ^2 of the fit. All χ^2 values are near 1, indicating that the model fits the data. The errors listed for the thickness are all small, showing that the film thickness is a very well determined parameter for these data sets. The parameter *A* is a measure of the SiO₂ refractive index, showing that thin-film SiO₂ can have a slightly larger refractive index than bulk fused silica.

Enantiomeric Purity Studied Using NMR

Thomas J Wenzel, Bates College Lewiston, ME USA

Introduction

Living organisms have a remarkable ability to distinguish enantiomers. Enzymes and cell surface receptors are handed, such that enantiomers often exhibit different properties in living systems. In extreme cases one enantiomer might be beneficial to a living organism, whereas the other might be harmful. Therefore, it is critical that methods exist to determine the enantiomeric purity and assign absolute configurations of chemical compounds. Various types of chiroptical spectroscopy are used for this. NMR spectroscopy is one of the most common and powerful methods for the determination of enantiomeric excess (typically to 1% of the minor enantiomer) and absolute configurations. There are generally considered to be three broad categories of reagents suitable for chiral resolution in NMR spectroscopy: chiral derivatizing agents, chiral solvating agents, and lanthanide shift reagents.

Chiral derivatizing agents are optically pure compounds that undergo reactions with the enantiomers being analysed. Most derivatization reactions involve the formation of covalent bonds; however, some examples, most notably with carboxylic acids and amines, rely on the formation of soluble salts. The resulting complexes are diastereoisomers, which may then exhibit different chemical shifts in their NMR spectra. Derivatization agents must react quantitatively with both enantiomers, with complete retention of configuration of both the substrate and resolving agent or with complete stereospecificity of any perturbations that occur. Useful chiral derivatizing agents usually have a discrete and specific NMR signal (e.g. a methyl group, fluorine, or phosphorus singlet in the ^1H , ^{19}F , or ^{31}P NMR spectrum) that is conveniently monitored for enantiomeric resolution. Most chiral derivatizing agents function with compounds that are readily modified, such as amines, alcohols, and carboxylic acids. In many instances it is possible to assign absolute configurations either by observing trends in the data on similar families of compounds, or through a detailed analysis of the geometric differences that lead to distinctions in the chemical shift values of the diastereoisomers.

Chiral solvating agents are additives that react *in situ* with the compound being analysed. Rather than forming covalent bonds or ion pairs, chiral solvating agents associate with the substrate through combinations of van der Waals forces. Hydrogen bonding, charge-transfer

complexation of electron-rich and electron-deficient aromatic rings, and steric effects are important interactions. The change in chemical shifts that occur in the spectrum of a compound in the presence of a chiral solvating agent are denoted as $\Delta\delta$. The extent of enantiomeric resolution that might then be observed for a shifted resonance is denoted as $\Delta\Delta\delta$.

Chiral solvating agents function by two possible mechanisms: Equations [1] and [2] represent the association of a pair of enantiomers with a chiral solvating agent (CSA), in which K_R and K_S denote the association constants for the *R* and *S* enantiomers

respectively. These reactions should occur rapidly on the NMR time scale such that the spectrum of the substrate is a time average of the bound and unbound form. A typical observation is that K_R and K_S are not equal, so that one enantiomer spends more time free in the bulk solvent than the other. The different time-averaged solvation environments may result in differences in the NMR spectrum. In addition, the two complexes (*R*-CSA and *S*-CSA) are diastereoisomers and therefore can have different chemical shifts irrespective of the relative magnitude of the association constants. In many cases, it is reasonable to assume that both mechanisms partially contribute to the enantiomeric resolution. It is sometimes possible to determine which of the two mechanisms predominates. With certain chiral solvating agents, the mechanism that leads to the enantiodiscrimination is well understood and absolute configurations can be assigned on the basis of the relative shifts.

Enantiomeric resolution with chiral solvating agents is dependent on the relative concentrations of the reagents. Usually, enantiomeric resolution is best when the concentration of solvating agent is greater than or equal to that of the enantiomers. Temperature is also an important variable. Lowering the temperature usually, but not always, increases the association of solvating agent and substrate, thereby increasing the enantiomeric resolution.

Lanthanide shift reagents are in actuality chiral solvating agents; however, their behaviour is in some ways unique and they are typically considered a separate category of chiral resolving agents. Chirality is achieved

by complexing the lanthanide ion with a chiral ligand. Electron-rich hard Lewis bases (typically oxygen- and nitrogen-containing compounds) interact through a donor-acceptor process with the positive lanthanide ion. Binuclear lanthanide-silver complexes have been developed for use with soft Lewis bases such as olefins, aromatics, phosphines, and halogenated compounds. With the binuclear reagents, the soft Lewis base associates with the silver ion.

Paramagnetic lanthanide ions induce substantially larger shifts, and often larger enantiomeric resolution, than is observed with other chiral derivatizing or solvating agents. Enantiodiscrimination can occur because of differences in association constants and/or because the resulting complexes are diastereoisomers. An advantage of lanthanide shift reagents is the broad range of compounds for which they are potentially effective. A disadvantage is that the chiral ligands in the lanthanide complexes are not geometrically rigid but instead are conformationally mobile. As a substrate binds, the chiral ligands alter their spatial position to accommodate the additional ligand. This effectively eliminates the ability to understand the basis of the enantiodiscrimination at the molecular level, so that assigning absolute configurations is difficult and only accomplished by observing trends on similar compounds with known configurations.

Chiral Derivatizing Agents

Perhaps no reagent for enantiomeric resolution is more widely known than α -methoxy- α -trifluoromethylphenylacetic acid (MTPA), otherwise known as Mosher's reagent [1]. Either the acid or acid chloride form is suitable for derivation of alcohols into esters and amines into amides. MTPA possesses all the classical features of an effective chiral derivatizing agent. The methoxy singlet in the ^1H NMR spectrum and the trifluoromethyl singlet in the ^{19}F NMR spectrum often show enantiomeric resolution. Enantiomeric distinction is usually observed only when the site of chirality is near the hydroxy or amine group at which derivatization occurs. In addition, by analysing the geometry of the resulting derivatives, it is often possible to explain the order of shifts in the ^1H NMR spectrum. An example is shown in **Figure 1** for the MTPA derivatives of secondary carbinols and primary amines.

A variety of chiral resolving reagents that are structurally similar to Mosher's reagent have been reported. These include examples in which the phenyl group of [1] has been replaced with naphthyl or anthryl groups; the methoxy group with acetoxy, methyl, ethyl, or hydroxy groups or a fluorine atom; or the trifluoromethyl group with a cyano group or a hydrogen atom. Collectively, these reagents are effective for amines, alcohols, β -amino alcohols, and thiols. Several have been used to resolve the spectra of amines through the formation of diastereoisomeric salts.

Figure 1 Configurational correlation model for (*R*)-MTPA and (*S*)-MTPA derivatives of secondary carbinols and amines. Reprinted with permission from Dale JA and Mosher HS (1973) Nuclear magnetic resonance enantiomer reagents. Configuration correlations via nuclear magnetic resonance chemical shifts of diastereomeric mandelate, *O*-methylmandelate, and α -methyl- α -trifluoromethylphenylacetate (MTPA) esters. *Journal of the American Chemical Society* 95: 512–519. Copyright (1973) American Chemical Society.

The compounds α -methoxy- α -(1-naphthyl) acetic acid and α -methoxy- α -(9-anthryl) acetic acid, which possess a more sterically hindered group than [1], often provide a larger degree of enantiomeric resolution in the NMR spectra and can be used to analyse compounds with more remotely disposed chiral centres. The ^{19}F NMR spectrum of derivatives of α -cyano- α -fluoro-phenylacetic acid, in which the fluorine atom is closer to the chiral centre than in MTPA, show enantiodiscrimination in compounds with remotely disposed chiral centres. Enantiomeric excesses of primary alcohols that are highly hindered or have the asymmetric centre at the β carbon have been determined using a sterically hindered compound such as α -methoxy- α -(9-anthryl)-acetic acid.

The choice of solvent is critical when diastereoisomeric salts are formed. Polar solvents solvate the ions, thereby inhibiting ion pair formation and reducing enantiomeric resolution. Non-polar solvents such as chloroform or benzene are preferable. A similar observation occurs as well with many chiral solvating agents and lanthanide shift reagents, and non-polar solvents are preferred.

Axially chiral carboxylic acids such as [2] and [3] can be used to prepare diastereoisomers of secondary alcohols. The NMR spectra of the diastereoisomers show enantiomeric resolution and it is possible to assign absolute configurations. Monocyclic, chiral carboxylic acid compounds such as tetrahydro-5-oxo-2-furancarboxylic acid and 2,2-diphenylcyclo-propane-carboxylic acid have been used to derivatize secondary alcohols for the purpose of enantiomeric resolution. Similarly, bicyclic derivatizing agents such as camphanic acid, camphanic acid chloride, or camphor sulfonyl chloride have been used to derivatize amines or alcohols to their respective amides or esters for the purpose of enantiomeric resolution.

By using optically pure alcohols such as methylmandelate, α -phenylethanol, 2-(trifluoromethyl)benzhydrol, 1,1'-binaphthalene-8,8'-diol, or ethyl 2-(9-anthryl)-2-hydroxyacetate, or optically pure amines such as methylbenzylamine, (1-naphthyl)ethylamine, 9-(1-aminoethyl)anthracene, 2-(diphenylmethyl)pyrrolidine, 1,2-diphenyl-1,2-diaminoethane, or 9-(1-amino-2,2-dimethylpropyl)-9,10-dihydroanthracene as the chiral derivatizing agent, it is possible to assess the enantiomeric purity of chiral carboxylic acids. Amine derivatives of the naturally occurring monoterpene (+)-3-carene have been used for this purpose as well. In certain cases it is possible to assign absolute configurations with these reagents.

Whereas there are a wide variety of effective chiral derivitizing agents for amines, alcohols, and carboxylic acids, there are considerably fewer options for ketones. The absolute configuration of six-membered cyclic ketones can be determined using butane-2,3-diol or the related 1,4-dimethoxybutane-2,3-diol. Enantiomeric

resolution is observed in the ^{13}C or ^1H NMR spectra of the resulting butane-2,3-diol acetal. Absolute configurations can be assigned according to the model in **Figure 2**, provided the cyclohexane ring of the acetal has a preference for the chair form. The model does not work for acyclic ketones, cyclopentanones, or cycloheptanones.

The ^{31}P nucleus is especially well suited for observing enantiodiscrimination in diastereoisomers and a variety of phosphorus-containing chiral reagents (**Figure 3**) have been developed [4]–[11]. Certain of these reagents [5, 6, 8] function with chiral primary alcohols. A particularly interesting example is the use of [8] to resolve

Figure 2 (a) The model, (b) both enantiomers of 3-methylcyclohexanone acetalysed with (2*R*, 3*R*)-butane-2,3-diol and fitted in the model, and (c) both enantiomers of 2-methylcyclohexanone acetalysed with (2*R*, 3*R*)-butane-2,3-diol and fitted in the model. Figure 3 Phosphorus-containing chiral derivatizing agents. [4] 2-chloro-3,4-dimethyl-5-phenyl-1,3,4-oxazophospholidene-2-sulfide; [5] 2-chloro-4,5-dimethyl-1,3,2-dioxaphospholane-2-oxide; [6] 2-dimethylamino-1,3-dimethyloctahydro-1H-1,3,2-benzodiazaphosphole; [7] 5,5-dimethyl-2-hydroxy-4-phenyl-1,3,2-dioxaphosphonan-2-oxide; [8] L-menthyl(phenyl)phosphoryl chloride; [9] 2-chloro-1,3-dimethyl-4,5-diphenyl-1,3,2-diazaphosphole; [10] dichloro(menthyl)phosphine.

the ^2H and ^{31}P spectra of derivatives of $[1-^2\text{H}]$ ethanol (CH_3CHDOH). Other of the phosphorus-containing reagents function with amines, secondary or tertiary alcohols, and thiols. The phosphoric acid derivative [7] can be used to resolve amines through the formation of diastereomeric salts.

The ^{77}Se nucleus has a spin of $1/2$, reasonable natural abundance (7.5%), adequate sensitivity (6.98×10^{-3} compared with ^1H), a large chemical shift range, and is extremely sensitive to its electronic environment.

Compound [12] is an effective chiral derivatizing agent for chiral carboxylic acids. Compounds such as 5-methylheptanoic acid and lipoic acid, which have remotely disposed chiral centres, and α -deuteriophenylacetic acid, which is enantiomeric by virtue of replacement of a hydrogen atom with deuterium, show enantiomeric resolution in the ^{77}Se NMR spectrum upon derivatization with [12].

Metal complexes other than the lanthanides can sometimes be used to effect chiral resolution in the NMR spectra of enantiomers. Zinc porphyrins with chiral ligands have been used to distinguish N-substituted, anionic amino acids and amino acid esters. Techniques such as NOESY and ROESY can be used to determine relative interatomic distances. In metal complexes containing a chiral ligand of fixed geometry, such techniques can be used to definitively establish the absolute configuration of the ligand.

Chiral metal cations such as $[\text{Ru}(\text{bipy})_3]^{2+}$ and $[\text{Ru}(\text{phen})_3]^{2+}$ can be enantiomerically resolved through the formation of diastereoisomeric salts with [13]. Both the metal complex and [13] possess D_3 symmetry, which presumably accounts for the discriminating interactions.

Chiral Solvating Agents

The first application of a chiral solvating agent involved the observation of distinct ^{19}F NMR resonances for 2,2,2-trifluoro-1-phenyl ethanol [14] dissolved in (*R*)- α -phenylethylamine. Optically pure [14] has since been

Figure 4 Association of racemic sulfoxides and lactones with 2,2,2-trifluoro-1-phenyl ethanol [14] and 1-(9-anthryl)-2,2,2-trifluoroethanol [15].

Figure 5 Interactions proposed to account for the retention of the more highly associating enantiomer in [16] and [18]. Reprinted with permission from Pirkle WH, Murray PG, Rausch DJ, and McKenna ST (1996) Intermolecular ¹H-¹H two-dimensional nuclear Overhauser enhancements in the characterization of a rationally designed chiral recognition system. *Journal of Organic Chemistry* 61: 4769-4774. Copyright (1996) American Chemical Society.

applied more widely as a chiral solvating agent for a range of compounds, including oxaziridines, *N,N*-dialkyl arylamine oxides, and sulfoxides. (*R*)-(1)-(9-Anthryl)-2,2,2-trifluoroethanol [15], which is similar to [14], is often a better chiral solvating agent than [14]. Compound [15] is also effective with γ -lactones. **Figure 4** shows the association of racemic sulfoxides and lactones with [14] and [15]. Shielding of the aryl group causes the group *cis* to it to occur at higher field than the enantiomer with the same group in the *trans* position. Similar structural considerations explain the relative shift orders in the spectra of oxiridines and *N,N*-dialkylarylamine oxides in the presence of [14] and [15].

3,5-Dinitrobenzoyl derivatives of leucine [16] and phenylglycine, and 1-(1-naphthyl)ethylurea derivatives of amino acids such as valine, leucine, and *t*-leucine [17] were originally developed and exploited in the liquid chromatographic separation of enantiomers. The chromatographic phases are potentially suitable for separating thousands of different enantiomers. Organic-soluble analogues, achieved by the conversion of the acid functionality into an ester, are useful NMR chiral solvating agents for a wide range of

substrates. The related 3,5-dinitrobenzoyl derivative of phenylethylamine is also useful as a chiral solvating agent. The dinitrobenzoyl ring is especially suited to charge-transfer complexation with aromatic residues of the substrate, the amide functionalities provide sites of partial negative and positive charges, and the R group of the amino acid provides a site for steric hindrance. The naphthyl ring of [17] and the aromatic moiety of the proline-containing reagent [18] will form charge-transfer associations with compounds that have been converted into their dinitrobenzoyl derivatives. **Figure 5** shows the interactions of aromatic rings and hydrogen bonding groups that occur between [16] and [18].

Aromatic diols such as [19] and [20] are axially chiral. Compound [20] is an especially effective chiral solvating agent for sulfoxides, phosphine oxides, alcohols, lactams, and amines. With sulfoxides, it is possible to assign absolute configurations. Quinine has been used as a chiral solvating agent for hemiacetals and β -hydroxyesters. The compound *t*-butylphenylphosphinothioic acid [21] is a useful chiral solvating agent for a broad range of compounds, including tertiary amine oxides, alcohols, thiols, and amines.
